of carbon bisulphide; the second requires a little more warmth of the hand to thoroughly clear it; while the third remains slightly opalescent, unless a higher heat than that of the hand is applied. The first and second acids on the table are miscible with as much as 15 times their volume of turpentine (and probably with much more), but the third shows distinct opalescence when mixed with four times its volume of that reagent. Thus the carbon bisulphide and turpentine tests, if applied as described, can only detect the presence of two or more per cent. of water in acetic acid.

We have not yet made any systematic experiments with the colour tests for oils, but a few were made with Pattinson's modification of Bechi's nitrate of silver test for cotton-seed oil. The rape oils in the table all give a more or less darkening of colour, but the olive and arachis oils are not affected. Too much dependence is often placed on these tests generally, and a thorough revision is required in order to determine their exact value, and under what circumstances they are valid and not open to objection.

DISCUSSION.

The CHAIRMAN said that Messrs. Thomson and Ballantyne had gone into the subject with their usual accuracy. He thought they had shown the great difficulty there still was in finding a really good test to distinguish a certain oil in the presence of another.

Dr. G. G. HENDERSON said that this was one of those papers which one could not discuss on merely hearing it read, while at the same time it was a paper of the utmost value to all interested in the examination of oils, and this for two reasons, firstly, because it put aside misconceptions, and secondly, because it gave positive information on different points. His object in rising was not to criticise the paper, but simply to say a word in praise of the very ingenious modifications in Maumene's test, which had been shown. It had always seemed to him that this test was in an unsatisfactory condition, as one could easily see from the second table, where it was shown that a very small difference in the strength of the sulphuric acid made a large difference in the rise of temperature.

Mr. J. PATTISON said he should like to ask if Mr. Thomson could give any explanation of the variation in the iodine absorptions of the linseed oil. Were these entirely different kinds of linseed oil? Also the variation in the iodine absorption in the mineral oil seemed to be very great. Were these oils obtained from different sources, and were their gravities different?

Mr. R. T. THOMSON, in reply, said that the modifications in Maumene's test of which he spoke were due to Mr. Ballantyne. With reference to Mr. Pattison's remarks the variation of the linseed oils was very great. They had some pure oils lower indeed than 173 in iodine absorption. He might mention that the highest one, 187.7, was Baltic oil, the 178.8 was East Indian oil, the 175.5 was River Plate oil, and of the lowest one he did not know the source. With regard to the mineral oils the gravities varied pretty much as shown in the table. The one with 8.7 of iodine absorption was a Russian oil, the one with 26.1 was a Scotch mineral oil, and of the third with 12.8 he did not know the source.

Meeting held in the Philosophical Institution, Edinburgh, on Tuesday, February 3rd, 1891.

DR. J. B. READMAN IN THE CHAIR.

ON THE CORROSION OF IRON.

BY ROBERT IRVINE, F.C.S., F.R.S.E.

THIS may well be called the "Iron Age," for it would be as difficult to point to any structure or mechanical appliance from which iron is absent as it would be tedious to enumerate the multitudinous uses in which it is employed at the present day.

In olden times it was valued above gold and silver. At the present time its initial value is a mere trifle (even in its purer forms), but its true value lies in its almost universal adaptability.

The subject, therefore, of its corrosion is of such vast importance that I have gathered together a few "out of the common" instances of the destruction of its useful properties.

The processes of smelting deprives the ore of the oxygen and other bodies with which the iron is combined, and at the same time adds to it impurities which make it less able to withstand corrosion, subsequent fusion with basic bodies and air being necessary to deprive it of these impurities. Curiously enough cast iron is less subject to oxidation than the purified wrought iron or steel. This is in part due to the silicious skin formed by the combination of the molten iron with the sand of the mould.

Their comparative liability to oxidation according to Mallet is as follows:—

Cast iron.....	100
Wrought iron.....	129
Steel.....	134

According to Gmelin the purest iron rusts most quickly, and the presence of sulphur and iron accelerates the rusting, whilst phosphorus seems to retard it. It is only when exposed to damp air containing carbonic acid that rusting or oxidation takes place, due, according to Calvert's observation, to galvanic action, protoxide, and subsequently carbonate of the protoxide, being formed, which in turn is changed to sesquioxide by the absorption of oxygen; ammonia being at the same time formed from the nascent hydrogen of the decomposed water and the nitrogen of the air.

A second form of corrosion is familiar to us when iron is exposed to the smoke of cities containing a large proportion of sulphurous and carbonic acids, which, forming soluble salts with the iron, are removed by water. Sea-water, on account of the quantity of magnesium salts and carbonic acid present, has a powerful solvent action on cast and wrought iron. Besides this, when iron is exposed to the action of sea-water in the presence of dead or decomposing organic matter, owing to its well-known action in the deoxidation of alkaline and earthy sulphates—

sulphide of iron is produced. A familiar example of this process occurs in the muds of tidal rivers and harbours, the iron present in the clay combining with the liberated sulphur to form sulphide of iron, and we may assume from this source most of the iron pyrites deposits take their origin.

A typical instance of this kind of corrosion came under my notice when removing an iron chain which had been used as a mooring in sea-water. When taken from the water it was thickly coated with living and dead animals. The sulphur from the deoxidised sulphates had combined with the metallic iron to form a skin fully an eighth part of an inch in thickness, and the chain was correspondingly weakened to this extent.

Of another form of the corrosion of iron, evidently due to galvanic action set up between two forms of the same metal, we have many instances. In one case the pans in which crude saltpetre was dissolved were made of cast, whilst the steam pipes and stirrers were made of wrought iron. The cast iron was unaffected, but in a short time it was found the wrought-iron fittings had become so corroded or wasted away that they had to be replaced. On cast-iron pipes and fittings being substituted the corrosion ceased.

Again, wrought-iron boilers in combination with cast-iron pipes, are used for heating purposes. The boiler is rapidly wasted away and rendered useless. In the same manner the cast-iron fittings of the steam boiler tend to corrode the portion of the malleable iron upon which they are fixed.

In the fitting of propellers for steam vessels the former are usually made of cast, and the tunnel shaft of malleable iron. After a time the propeller becomes loose on account of the combination of the two unlike metals causing corrosion of the same nature.

When malleable iron rails are fixed in iron sleepers, as on our railways, the corrosion of the weaker metal is very apparent. The serious nature of this action is exemplified in the following extract from *Engineering* of December 1890—

"An important fact in regard to the wear of railway rails is notified, and illustrated in the last number of the *Engineer*. Two sections of the same rail are given showing the comparative wear of the rail, in a period of seven years, in a tunnel, and on the open railway. The difference is very remarkable. The rail laid in the tunnel has lost nearly half the area of the lower flange, the rounded extremities are pared down to knife edges, and about one quarter of the area of the upper flange is eaten away, more on one side than the other, leaving an irregular-shaped mass. This alarming increased wear and disintegration in the tunnel is, of course, due to atmospheric causes; but if this case is taken as establishing the general tendency of rails to behave in this way in tunnels, it is a fact of serious importance in regard to the laying and maintenance of tunnel roads. A tunnel is exactly the place where one may suppose that a defective condition of the rails might most easily escape observation; yet it appears that this is where it is most likely to occur within a given space of time."

and tear

Musconetcong tunnel, Lehigh Valley Railway, nr. New York.

From *Engineer*, 1890, p. 539.

The "atmospheric causes" here clearly point to this example of corrosion as of the same category as those already mentioned.

In connexion with this subject it is abundantly manifest that the use of two dissimilar forms or kinds of iron becomes a source of danger and loss.

If plates of cast and malleable iron are placed in water, and wires from each connected with a galvanometer, deflection of the needle at once takes place, whilst if both plates be either of cast or malleable iron no galvanic action ensues.

It naturally follows that any structure if it is to be free from the danger I have referred to should be composed of the same variety of iron; and, by observing this matter (although a very simple rule), the constructors of the Forth Bridge, where mild steel was used throughout in its construction, have doubtless avoided the mistake made in the construction of the old Tay Bridge, which was a combination of cast and malleable iron, neither being of very good quality. After its destruction, the commission appointed by Government to inquire into the cause of its collapse found that the rivets of the malleable iron portion had become loosened, and the evidence all pointed in the direction that this bridge was so constructed that it formed a huge galvanic circle in which the malleable iron was weakened beyond the point of stability.

The universal use of paint in the preservation of such structures is well known, but I consider the use of all metallic pigments has a tendency, wherever the iron is not thoroughly covered, to provoke the danger they are intended to remedy.

A varnish such as boiled linseed oil alone, which, on exposure to air, dries up into a tenacious elastic coating, seems to me to be the proper material to be used for the protection of iron structures.

DISCUSSION.

Mr. D. B. Dorr said that, for the protection of iron, he thought that turpentine was coming to be recognised as the best material for the first coating, which should be followed up with a drying oil.

THE CHAIRMAN said he was glad to learn that steam boilers should be made entirely of the one material; viz., malleable iron. He had noticed that in the blow-off pipe of a steam boiler that the cast-iron pipe, which was connected with the malleable iron boiler, was very often corroded. It was also interesting to see the sketch of the rails that had been submitted, showing the marked difference in the wear and tear of the rails inside and outside of the tunnel.

The Purification of Water for Industrial Purposes.
M. Zabrowski. Bulletin des Fabricants de Papier and Chem. Trades J. 8, 39.

THE author publishes two new methods for the softening of water, which are stated to give satisfactory results.

In the first process, hydrated baryta is placed in a filter press which is traversed by the water to be purified and produces an effluent, showing only 1 or 2° of hardness. Hydrated baryta, which is now largely used in sugar

* Any of these specifications may be obtained by post, by remitting the cost price, plus postage, to Mr. H. Reader Luck, Controller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. The amount of postage may be calculated as follows:—

If the price does not exceed 8s.	½d.
Above 8s., and not exceeding 1s. 6d.	1d.

" 2s. 4d., " " " 3s. 4d.	2d.

refining and is easy to procure, precipitates all the bases, lime, magnesia, &c., as well as the sulphuric and carbonic acid, so that the carbonates and sulphates of lime and magnesia, which are the most harmful substances, are precipitated by one treatment.

According to the other process, hydrated oxide of lead is employed instead of baryta and precipitates the carbonates, sulphates, and chlorides. It is necessary to obtain the hydrated oxide of lead cheaply, and the following ingenious method has been devised by Villon for this purpose.

A solution of sodium nitrate is placed in a vat, divided into two compartments by a diaphragm; lead electrodes of large surface are placed in the solution and the current from a dynamo then passed through. The sodium nitrate is decomposed, caustic soda being formed in the negative compartment and nitric acid at the positive pole, from which it dissolves a certain quantity of lead, forming lead nitrate. When the current has passed through the liquid for a certain time, the solutions are run from the two compartments into a second vat and there mixed by means of an agitator. The soda precipitates hydrated oxide of lead and itself forms sodium nitrate; the solution is then filtered and the nitrate solution again submitted to electrolysis. When the baryta or lead oxide is used up, it is replaced by freshly prepared oxides.

The purification by barytes is more perfect than that by lead oxide. According to Villon, the use of the filter press can be avoided by employing plumbate of sodium (a solution of lead oxide in caustic soda). The precipitate is simply allowed to settle out, and the water obtained shows a hardness of about 2° or 3° .

PATENTS.

Improvements in Apparatus for Concentrating Solutions, Drying Substances, and like purposes. D. Herman, St. Helens. Eng. Pat. 20,049, December 13, 1889. 6d.

A CIRCULAR pan has flanges which dip down into the liquid, gaseous pressure being used beneath it to carry the main weight of it, the residual weight being carried by rollers or other device. The pan is caused to rotate by any convenient means, and is enclosed in a furnace, in which heated gases and products of combustion, preferably from gaseous fuel, pass over the pan. The furnace is so constructed that a portion of the pan projects beyond the walls, in order that access can be obtained to every portion of it during its rotation. Scrapers are used for moving solid matter from the centre towards the circumference.—E. S.

Improvements in Furnaces for Burning Tan and other Refuse Material. C. A. Brown, Exeter. Eng. Pat. 1170, January 22, 1890. 6d.

VERTICAL pockets or chambers are made in the side walls of a furnace and filled with tannin refuse. By means of a weighted cover placed upon the top the material is pressed down and continuously fed into the bottom of the furnace.

Two or more furnaces may be built side by side so that the pockets may discharge into two adjacent furnaces, in which case a larger pocket must be used.—D. A. S.

Improvements in or Connected with Apparatus for Filtering Liquids. A. Capillery, Vigan, France. Eng. Pat. 1307, January 24, 1890. 1s. 1d.

THIS invention relates principally to the shape and arrangement of the channels on plates for filtering presses, set out with a view to provide for the proper distribution of the liquid over the whole filtering surface. It refers to several ways of grouping and holding the plates together, and also gives various designs for grids to be placed between the

filtering cloths, one of which is indicated in the accompanying figure:—

PLATE FOR FILTER PRESS.

When the plates are placed in position, with the necessary filtering cloth between, and tightened up by a screw or screws, their circumferences may either form a continuous closed receptacle for the retention of the liquor, or they may be of a construction to require insertion into another closed vessel. There are seven claims and three sheets of drawings.—B.

Improvements in Apparatus for Separating Liquids from Solids. H. W. Deacon and V. C. Driffield, Widnes. Eng. Pat. 1948, February 5, 1890. 6d.

A VESSEL in the form of a perforated truncated cone has its larger end downwards. The upper end is closed by a cover, preferably dished, and securely attached to the cone. The lower end is closed by a cover, also dished, and of such a size as to leave the full area of the cone so as not to impede the discharge, by gravitation, of the solid filtered material when the cover is removed. This cover, as well as the vessel, is lined with filtering medium. The material to be treated, in the form of a mixture of solid and liquid, is admitted through a pipe, which passes through the upper cover, until the desired pressure is attained. This pipe is perforated and extends nearly to the bottom of the vessel, and at a subsequent part of the process can be used as a siphon to withdraw a certain amount of unfiltered liquid, and thus loosen the solid material from the walls of the vessel. The solid material is discharged by the removal of the lower cover, and should it fail to fall out, steam, admitted through a small pipe passing through the upper cover, hastens the discharge. The filtered liquid may be collected in a moveable tray placed under the conical vessel.—E. S.

Improvements in the Treatment of Solutions or Liquids for the Purpose of Concentration or Evaporation, and in Apparatus therefor. A. Fryer, Wiltshire. Eng. Pat. 2427, February 14, 1890. 8d.

THE inventor constructs apparatus for evaporating or concentrating liquids at low temperatures, by employing a conical metal dish, very shallow, and fitted with a slight rim all round the edge. The dish is secured with its centre to a spindle placed at a slight angle with the perpendicular, from which it deviates to the extent of the angles formed by the sides of the cone, so that, thereby, one of those sides is made to assume the horizontal position. Into the small cavity formed by the horizontal segment of the dish and by part of the projecting rim, the concentrating liquor is fed, whilst heat is at the same time applied underneath that part. On the rotation of the spindle with the dish, the inner surface of the cone takes up a thin film of the liquid and carries it all round the circle for the purpose of evaporation, which is further assisted by the action of air fans. A renewed film is carried off with every revolution, and the continuous withdrawal of the surface of the cone from the neighbourhood of the source of heat conduces to evaporation at low temperature, and prevents damage to delicate substances through excess of heat. The dish may receive heat at several points, and this, combined with regulation of the speed and of the supply of liquor and air, admits of very accurate adjustment to the required temperature. There are two drawings and four claims.—B.

Improvements in Centrifugal Machines. J. Murray, London. From "La Société Nouvelle des Raffineries de Sucre de Saint Louis," Marseilles, France. Eng. Pat. 2774, February 20, 1890. 8d.

This invention relates to centrifugal machines employed in treating sugar or other substances, and is specially adapted for continuous working by causing the filtering surface to travel along with the material which is pressed against it, and which is thus kept continuously cleared from obstructions; this renders the machine more effective, as well as uniform in action. A revolving drum is divided into six compartments, each in the form of the sector of a circle. At its outer or widest part, two horizontal rollers are mounted, one at the top, the other at the bottom, and around them passes a web of filtering fabric, which is supported against the centrifugal force by vertical rods. The two rollers being moved by suitable gearing, the inner surface of the filtering fabric is caused to travel upwards, and in so doing it receives at its lower part the water for washing; the central portion receives the material to be filtered, whilst steam is received at its upper part. As the inner surface ascends, it carries the material with it and discharges the liquid into a compartment between the rollers. As the outer surface travels downwards the solid material it carries is thrown by centrifugal action into the stationary case and discharged. A brush near the lower roller clears the filtering fabric before it re-ascends.—E. S.

Improvements in and relating to Evaporating Apparatus. R. Harvey, Glasgow. Eng. Pat. 3907, March 12, 1890. 8d.

This invention relates to the shape and position of steam and vapour inlets, and to the use of deflecting plates in tubular upright multiple-effect evaporating apparatus, and can be made clear only in connexion with the drawings and description of the specification.—B.

Improved Apparatus for Separating Liquids or Solids from Vapours or Gases in which they are Suspended. E. Jones, Leeds. Eng. Pat. 4594, March 24, 1890. 6d.

This invention is intended to produce the effect known as "drying steam," but can be applied generally to the separation of liquids or solids from vapours or gases in which they may be suspended.

The apparatus consists of a chamber, preferably square in cross section, in which are two series of inclined, transverse parallel blades or deflectors arranged intermediate at a certain distance apart, and forming a sinuous course for the steam. The wet steam enters the separator with a certain velocity, and striking against the blades, causes the watery particles to be deflected and run out through suitable openings in the lower series of blades. This action being repeated at each blade the steam is sufficiently deprived of its moisture.—E. S.

Apparatus for Drying Sugar or Like Substances. R. Pallas, Brieg, Germany. Eng. Pat. 10,893, July 12, 1890. 6d.

See under XVI., page 264.

Improvements in or appertaining to Mercurial Pumps. W. P. Thompson, Liverpool. From Dr. A. Raps, Berlin, Germany. Eng. Pat. 11,807, July 28, 1890. 8d.

This invention has partly for its object an apparatus for automatically working mercurial pumps of any kind. It is here described as applied to Topler's air pump. The apparatus consists of a mercury reservoir connected with the pump by a flexible tube, and by a second tube from its upper part, with a three-way cock, connected with a pressure conduit or with the atmosphere. The mercury reservoir rests on one side of a balanced lever working on a pivot,

the other side carrying a short lever connected with the three-way cock, and also a counterbalance weight automatically adjusted to slide between two collars, according to the larger or smaller amount of mercury in the reservoir, which is thus brought alternately in connexion with the pressure conduit or the atmosphere. In the former case, the mercury is forced into the pump, and in the latter, the compressed air being allowed to escape, the mercury falls back to the reservoir by its own weight.—E. S.

Improvements in Distilling and Condensing Apparatus. H. H. Lake, London. From E. Bolton, Cincinnati, U.S.A. Eng. Pat. 17,718, November 4, 1890. 8d.

This invention comprises a combined distilling column and condenser, having an unusually large cooling surface for the vapour to come in contact with, formed by a series of coils preferably arranged one above the other. For most purposes three series are found to be sufficient. The coils of each series are connected alternately at their outer and inner ends, the upper coil of each being provided with an independent inlet for cold water, and each lower coil with an outlet for the hot water, and communicating with a common elevated receptacle. The vapour escaping from the still passes successively through the three series, and escapes through an outlet deprived of most of its heat and impurities. For fuller details of the construction and working of the apparatus the specification must be consulted.—E. S.

Improvements in or Appertaining to Liquid Strainers. J. McEwen, Manchester. Eng. Pat. 17,984, November 8, 1890. 6d.

The improvement consists in employing the sponge, or other elastic material used as a strainer, as a ready and efficient means for regulating the speed of filtration. This is done by compressing the sponge, or releasing it, by means of an external screw acting on a loose plate inside the strainer. The screw apparatus being supported by clips on lugs on the outside of the case, can be readily removed when the pressure is withdrawn, and the sponge or other material can be removed for cleaning or renewal.—E. S.

An Improved Compound for Preventing and Removing Incrustation in Steam Boilers. J. L. Wade, London. Eng. Pat. 18,151, November 15, 1890. 4d.

CAUSTIC potash and esparto grass are boiled in water until the grass is reduced to a pulp, when finely-powdered sumac is added, and the whole further boiled until converted into a homogeneous mass. To this is then added (each being in solution) potassium carbonate, potassium chloride, sodium silicate, Irish moss, and, lastly, creosote and green mineral oils. These being added, the mixture is converted into a pasty mass, and according to the variation in the composition will either solidify or remain semi-fluid on cooling. The quantities of the various ingredients vary according to the quantity and nature of the scale-forming impurities in the water and on the condition of the boiler.—E. S.

Improvements in Continuous Evaporating Apparatus. O. Schulz, Brieg, Germany. Eng. Pat. 18,751, November 20, 1890. 6d.

A CASE, provided with dome, gauge, and other suitable fittings, encloses the evaporating pans, placed one above another, and with their ends arranged alternately, and mounted on rollers. Angle-iron rims are secured to the pans and hold between them and the upper flanges of the pans, corrugated plates, by their edges, and slightly inclined to facilitate the flow of the liquid. The liquid to be evaporated is led by a pipe to the higher part of the corrugated plates, and flows through a passage at the lower end of the pan into the one below, and so through the series to

an outlet, being heated as it passes over the pans by steam admitted to them below the corrugated plates. One wall of the casing may be made removable for convenience in removing the pans, cleaning, &c.—E. S.

Improved Methods of and Apparatus for Evaporating and Concentrating Solutions. J. A. Morrell, Lansdale, Penn., U.S.A. Eng. Pat. 19,110, November 25. 1890. 8d.

THE inventor proposes to evaporate concentrating solutions that have hitherto been treated at low temperatures by exposing them to high temperatures, but so rapidly as to prevent any injury to the matter which is to be recovered from the liquid. The accompanying diagrams indicate one of the arrangements as proposed for saccharine matter.

APPARATUS FOR EVAPORATION AND CONCENTRATION.

The tube (1) is closed at the upper end except for a number of small perforations (7) just under the head. The heated solution enters at (2) and issues through the perforations under pressure. The jets impinge against a circular screen (9), and are atomised. The superheated steam-jacket (3), with inlet and outlet (5) and (6), surrounds pipe (1), and heats the liquid therein to above the normal boiling temperature, whilst the whole is enclosed in the chamber (11) surrounded by the steam-jacket (10) with inlet and outlet (16) and (17), which is kept at a still greater heat. The concentrated fluid or granulated matter which has been thrown down from the screen is withdrawn from the conical bottom through the outlet (12), and the fluid may be re-introduced for further manipulation. Heated and compressed air and gases may be introduced through (13) at the bottom of pipe (1) to aid in the dispersion of the liquid at the upper end, and the resulting vapours may be withdrawn in any desired way. The drawings show four different arrangements of apparatus in connexion with saccharine matter, milk, &c., and there are eight claims.—B.

Improvements in Vulcanisers. J. H. Gartrell, Penzance, and F. Knoefel, London. Eng. Pat. 20,005, December 8, 1890. 6d.

THE invention relates to improvements in dental vulcanisers in which a copper or other vessel is closed by a steam-tight lid. The vulcaniser is constructed of hammered or rolled copper in one piece throughout, and is preferably cylindrical. The top is thickened to form a shoulder, and has lugs to carry the lid. The lid is made of gun-metal or other suitable material. The drawing attached to the specification shows two methods of fixing the lid. In one it is attached to lugs on the vessel by means of a hinge, and is tightly clamped down in position by a screw passing through a moveable bow fixed on opposite sides of the vulcaniser. In the second

the lid is secured by two bent clamping levers working on other lugs on opposite sides of the vessel, and which when brought into position over the lid are kept there by a screwed collar worked by a handle. The lid is hinged to one of the clamping levers.—E. S.

Coal Separating and Washing Plant. Engineering, 1890, 51, 184—185, and Engineer, 1890, 71, 171.

THE increasing scarcity of good coal-beds in this country has rendered it necessary to consider the question of profitably working inferior or dirty seams of coal. A method, therefore, which would offer the advantage of freeing the coal from heavy and deleterious impurities, and at the same time practically avoiding all waste of coal, ought to merit attention.

Such a process is that devised by Lührig, which is carried out on the pit-bank, and consists of two distinct operations, carried out in (1st) a dry separation plant, and (2nd) a washing plant, where everything from nuts to the finest smudge is automatically operated upon.

The tubs on leaving the cars travel along a platform, and by means of tumblers discharge their contents on to jigger screens, where the large coal gravitates to picking tables or bands, while the small coal drops through into a storage bunker underneath, which is in communication with the washery. The larger pieces of shale or stone and intergrown coal are separated by hand on these picking tables, the stones being thrown into shoots leading to the waste heap, while the dirty pieces of coal are thrown by shoots to a coal-breaker, where they are broken up, the shale and brassy pieces being thereby detached from the fragments of coal, which latter are delivered to the storage bunker. The small coal from the storage bunker is raised by an elevator to the top of the building, where it is sorted in a revolving drum or screen into four different sizes, viz., nuts, beans, peas, and dust; this preliminary sizing greatly facilitates the subsequent washing.

The different sizes over $\frac{3}{16}$ in. pass through spouts into separate washing jiggers, which are specially designed to deal effectively with large quantities and with the pieces of coal intergrown with shale. To win all this coal, these nut washers separate, by means of their specific gravity, the several sizes of nuts into three classes: 1st, clean washed nut coal; 2nd, coal intergrown with shale or brasses, &c.; and, 3rd, "clean dirt." The clean nut and pea coal is delivered over drainers into hoppers ready to be loaded into waggons. The intergrown coal is conveyed by a worm to an elevator to be lifted and further broken up by a roller mill provided with rollers 16 in. wide and $29\frac{1}{2}$ in. in diameter. The broken product is rewashed on one of the nut jiggers and a clean coal obtained from it, the refuse passing to the pit.

The fine coal under $\frac{3}{16}$ in. size from the revolving screen passes, along with the overflow water from the nut-coal jiggers into a grader consisting of a series of pyramid-shaped boxes in which the current of water deposits the coal in different sizes according to its gradually decreasing velocity. These boxes supply through apertures in the bottoms of the pyramids the fine-coal jiggers which are provided with felspar beds through which the dirt settles to the bottom of the machine to be thence delivered to the refuse pit.

The clean coal from all the fine-coal jiggers is carried with the overflowing water from these machines to a small

draining drum, made of copper sheets with very small holes, which separates the pearl coal from the finest coal, the pearls being raised to a hopper for fine coal while the finest coal passes along with the dirty water into a sludge recovery apparatus, which is a very notable feature in this process. The apparatus consists of a travelling creeper which slowly works in a long pit extending underneath the fine-coal jigger floor and on which the finest coal dust continuously collects and is removed by an elevator to a suitable hopper while the water overflows at the further end of the sludge pit into the clear-water tank to be again used for washing along with a small supply of fresh water.

Modifications of the above process are arranged for producing coal for special purposes, viz., coke making, &c., and from various classes and mixtures. The loss of pure coal in the refuse varies from $\frac{1}{4}$ per cent. to 1 per cent.

—O. H.

PATENTS.

Improvements in the Production of Coke for Foundry and other Purposes. F. J. Jones, St. Albans. Eng. Pat. 11,920, July 26, 1889. 8d.

This invention is intended to produce from a comparatively poor coal a higher percentage of hard coke capable of bearing the burden in a blast furnace, than can be obtained in an ordinary beehive oven. The coking operation is effected by passing hot gaseous products of combustion over the charge of coal, forming a hard skin on the coke and serving to expel and carry off the sulphur and other products immediately there generated instead of permitting them to remain and become re-absorbed by the coke.

The coking chamber has, preferably, an inclined floor leading down to a door in front by which the coke may be withdrawn in a solid block. By this process coking can be effected at a lower temperature.—D. A. S.

Improvement in Burner or Apparatus for Burning Petroleum or other Oil or Volatile Fluids. H. Lindley and I. Browett, Salted. Eng. Pat. 11,226, July 12, 1889. 8d.

This is a Bunsen burner or apparatus for burning heavy oils so as to avoid the use of wicks and obtain a smokeless flame. The gas is caused to issue in jet-like form, and carries with it air for combustion, the air and gas being previously intimately mixed and warmed. The gas generator which is also described consists of a coil of wrought iron pipe.—D. A. S.

Improvements in Method for Effecting the Operations Involved in the Production of the Gas technically known as Water Gas, and the Apparatus therefor. B. H. Thwaite, Liverpool. Eng. Pat. 12,266, August 2, 1889. 11d.

By means of an automatic arrangement the periods of air blast, or steam and air supplied to fuel (for revivifying the fuel), and steam supply are controlled.

The water gas being forced into a holder raises it to a specific height, when by means of a projecting piece on the outside of the holder, a weighted lever is released, and falling down opens the air valves, closes the gas escape valve, and reverses the steam supply so that the latter sets in motion a Roots blower, or is turned into an aspirator or injects the air into and through the fuel. When the holder has descended a certain distance it commences to close the air valve and afterwards opens the steam and gas valves, and water gas is again produced raising the holder once more until it reaches a height sufficient to reverse the valve. In descending, a chain passing round the pulleys and attached to the holder and to a weighted lever opens the air, and also reverses the steam and gas supply. The air used is preferably superheated.

There is also a combined safety and reversal valve arrangement.—D. A. S.

Improvements in or connected with Apparatus for the Manufacture of Water-Gas, applicable for Gas Engines and other purposes. J. R. Paisley, Colnbrook. Eng. Pat. 15,797, October 8, 1889. 8d.

In this invention a producer is constructed of wrought iron or other suitable material lined with firebrick.

The openings by which the fuel is fed into the apparatus are closed by ball valves of sufficient weight to remain closed against the pressure of gas. Round the edge of the top of the producer there is a suitable water-tight flange for the purpose of retaining water to keep the top cool. Steam and air are forced in at the bottom, and the gas rises to the top and escapes through holes in such a way as to be led down through the outer part of the producer and become superheated, finally escaping through channels to the hydraulic main.

This superheating does away with the objection of excess of moisture, and further, an equable temperature is maintained by passing the gas through coils of pipe in a tank of water kept at an even temperature. By these means a gas of more uniform quality of gas is said to be produced.

—D. A. S.

Improvements in the Method of Generating Gas for Heating and other Purposes, and in the Apparatus used therefor. D. Dixon, London. Eng. Pat. 16,795, October 21, 1889. 8d.

This is an arrangement made by the combination of two gas producers, one working with up-draught and the other with down-draught, whereby the producer-gas obtained from the one can be caused to pass by means of a blast together with steam, through other fuel previously raised to incandescence in the adjoining producer. In this way, in addition to making water-gas by converting the steam into carbon monoxide and hydrogen, the incandescent fuel in the second chamber reduces the carbon dioxide which is always present in producer-gas into carbon monoxide, and converts the tarry and sooty hydrocarbons given off in the first chamber into permanent gases. A product is thus obtained having a higher percentage of heating material than ordinary producer-gas and free from tar and soot.

There are two sheets of drawings.—D. A. S.

Improvements in Coking, and in Coke Ovens and Plant connected therewith. T. D. Rock, London. Eng. Pat. 17,351, November 11, 1889. 8d.

This is an arrangement whereby any number of coking ovens or chambers are combined in a block in such a way that each oven or chamber with its thues, cooling chamber, &c. is entirely independent of any other, and can be put out of use for repairs without affecting the use of any other oven. Each oven is practically a gas retort, and the gases are removed either into a gas-holder or common supply pipe, and brought back for consumption at any one of the ovens.

To enable a start to be made, and in order to be able to regulate the temperature, one or more gas generators are also used.

Each charge is retained in a chamber adjoining the coking oven during the coking of the next charge, so that its waste heat may be utilised. The gases are moreover allowed to pass close to these cooling charges before combustion. It is claimed that the retention of the coke in this latter chamber from which air is excluded improves its condition.—D. A. S.

Improvements in Apparatus for Separating or Extracting Tar and other Impurities from Gas. Kukham, Hulett, and Chandler, Limited, and J. Chandler, London. Eng. Pat. 18,831, November 23, 1889. 6d.

This is an upright scrubber with horizontal plates for washing gas. In each plate is formed a series of holes which on their lower sides are provided with nozzles or

extensions adapted to dip into cups or trays arranged on the plate beneath them, which cups or trays are designed to be filled with water or other purifying liquid. For further details the specification must be consulted.—D. A. S.

Improved Means and Appliances for the Production of Pure Carbonic Oxide Gas. T. Williams, London. Eng. Pat. 19,996, November 27, 1889. 8d.

See under XX., page 270.

Improvements in Closing Devices for Vessels containing Inflammable Liquids. F. Deimel, Berlin, Germany. Eng. Pat. 19,132, December 3, 1889. 6d.

THIS device is meant to prevent explosions of inflammable liquids even when poured from a vessel into a fire. The vessel is provided with a stopper of cork saturated with paraffin to prevent shrinkage. Through the centre of the stopper passes a tube which only extends into the neck of the vessel. The lower end is plugged with wire gauze. The part outside the cork is provided with a lateral curved tube. The upper end is closed, except that it allows of the passage of a second narrower tube, which also passes

through the gauze plug and extends to the bottom of the vessel. At its lower end this second tube is slightly curved. The upper end rises higher than the spout and then curves back outside to below the lower end of the first tube. It terminates in a spherical head fitted with wire gauze.

—F. W. T. K.

An Improved Apparatus for Washing Gas. W. W. Horn, London. From C. W. Jarrell, Shelby, U.S.A. Eng. Pat. 788, January 15, 1890. 8d.

THIS is a scrubber for washing gas, having an inverted cup-shaped deflector above the inner end of the supply pipe. Circular inclined water shelves are arranged centrally within the vessel, one above another. Water is injected by means of spray pipes located above these shelves. The gas is thus caused to take a zigzag course in its passage upwards, and is washed by the spray.—D. A. S.

Improvements in Furnaces for Burning Tan and other Refuse Material. C. A. Brown, Exeter. Eng. Pat. 1170, January 22, 1890. 6d.

See under I., page 239.

Improved Method or Process for the Gasification of Fuels, and Apparatus therefor. W. L. Wise, London. From E. Solvay and L. Smet, Brussels, Belgium. Eng. Pat. 1349, January 25, 1890. 8d.

THIS gas generator is distinguished by having no grates which, however, are replaced by vertical walls along which the oxidation takes place. It has also a steam and air-superheating apparatus. The generator is shown in Figs. 1,

Fig. 1.

Fig. 3.

Fig. 2.

2 and 3, Figs. 1 and 2 being vertical sections at right angles to each other, and Fig. 3 a horizontal section of this arrangement. A is a chamber for the fuel to be gasified, which may be of annular or rectangular form. B shows the passages for steam or steam and air communicating with the lower end of the chamber A. C is the heating flue where part of the gases are burned with air to heat B. D is a pipe or collector for the gases produced. E is a coil for superheating the steam and air. The steam and air necessary for the gasification are caused to regenerate or absorb the heat carried off by the gases of distillation and combustion, and are then passed into the regenerator of the Ponsard or similar type, which is arranged as near as possible to the gas generator. The superheating is thus effected without additional cost, and the small quantity of air mixed with the steam is not sufficient to check the favourable part played by the steam in the production of ammonia, even at a high temperature. Thus solid fuels can be gasified into a cold rich gaseous product without any loss due to the conversion, and without cost, theoretically, for heating whilst producing a high yield of ammonia. The gases produced are capable of producing the highest temperatures and are not diluted with nitrogen like those from gas generators used with air alone.—D. A. S.

Improvements in the Construction of Apparatus for Generating and Burning the Vapours of Oil or other Combustible Liquids, and in the Arrangements of their Application to Lighting and Heating. B. J. B. Mills, London. From A. Seigle-Goujon, Lyons, France. Eng. Pat. 1883, February 4, 1890. 8d.

This invention relates to arrangements of apparatus for producing light and heat, which burn the vapours of combustible liquids and themselves generate these vapours as they are required.

For details the specification must be consulted.

—F. W. T. K.

Improvements in Apparatus for Heating Liquid and Gaseous Bodies. B. J. B. Mills, London. From A. Seigle-Goujon, Lyons, France. Eng. Pat. 2055, February 7, 1890. 8d.

The object of this invention is the intense heating of steam boilers or similar apparatus, and generally of liquid or gaseous bodies, without smoke by the use of Bunsen burners. Each burner is formed of a tube, trumpet-shaped at its entrance and contracted at its exit, and a number of them is so arranged that when placed one within the other without touching, to allow of the admission of air, they form a flue for the passage of the flame, which is supplied by a gas injector. The invention is adapted to the production of steam in ordinary and circulating generators. In the former the burners are simply placed in the middle of the liquid to be vaporised contained in an ordinary boiler; and in the latter the liquid to be vaporised circulates around the burners, which themselves form the generator. The modes by which this is effected is shown on the drawing accompanying the specification.—E. S.

Improvements in the Process of Treating Incandescents for Use with Gas Lamps or Burners. C. Bellwik, Hyde Park, Ill., U.S.A. Eng. Pat. 2110, February 8, 1890. 6d.

The luminosity of incandescent burners made of lime, alumina, magnesia, &c., is alleged to be increased by partially coating that part of the burner which usually becomes most intensely luminous with certain heavy metals of high conductivity, such as chromium, niobium, tungsten, cobalt, copper, platinum, or iridium, or with their oxides, or with mixtures of these oxides with certain substances which become highly luminous when incandescent such as the oxides of zirconium, yttrium, lanthanum, didymium, &c., or with the latter oxides alone. Coloured light may be obtained by the application of some of these oxides to the

burner, the oxides of chromium, tungsten and cobalt giving a yellow shade, copper, platinum and iridium a red shade, didymium a green shade, and so forth. The burners are prepared by painting them with a solution of the selected oxide, drying and firing at a high temperature.—S. B. A. A.

Improvements in the Manufacture or Treatment of Gases containing Carbonic Oxide, such as Water-Gas and Producer-Gas, to render them Odorous. F. Scudder and H. G. Colman, London. Eng. Pat. 2341, February 13, 1890. 4d.

To render water-gas odorous it is proposed to add a volatile organic sulphide produced by acting on acetone with sulphuretted hydrogen in presence of a dehydrating agent such as hydrochloric acid, with or without zinc chloride. The moderate quantity of steam used to carry the sulphide to the gas to be impregnated is sufficient also to volatilise the sulphide.

The volatile organic sulphide (thio-acetone, or sulphurised acetone) above referred to can be prepared by mixing 5 parts by weight of acetone (boiling point 133° – 137° F.) with 4 parts by weight of hydrochloric acid, sp. gr. 1.16, cooling the mixture to 60° F., and adding 1 part by weight of zinc chloride. This mixture, which should always be freshly prepared, is treated with sulphuretted hydrogen preferably in a series of vessels; if four vessels be used the first can be removed after the sulphuretted hydrogen has passed through for 8 or 10 hours, and a fresh vessel placed at the end of the series.

The resulting product contains an oil and an aqueous solution of which the former contains the larger quantity of thio-acetone. The oil can be drawn off or the raw mixture distilled in a current of steam at atmospheric pressure, the distillate being allowed to flow directly into an odourising reservoir.

The odour is perceptible and lasting and not liable to be lost, or appreciably diminished by condensation. The gas should be purified by hydrated iron to remove any free sulphuretted hydrogen.—D. A. S.

Improvements relating to the Carburetting or Enrichment of Coal and Other Gas, and to Apparatus therefor. H. S. Maxim, Crayford, and G. S. Sedgwick, London. Eng. Pat. 2559, February 17, 1890. 1s. 1d.

The main features of this invention are the following:—The gasoline, naphtha or other suitable hydrocarbon is admitted into the evaporating cylinder from a reservoir at a higher level by means of an automatic arrangement which only allows of the passage of the hydrocarbon when the evaporating cylinder has become and is being heated by the steam. The reservoir is kept supplied from a second one at a lower level by means of a pump. The hydrocarbon vapour is either forced directly into the main or into a branch which leads from and returns to the main by means of an injector. In the latter case the force with which the vapour escapes from the injector creates the necessary current of gas in the branch. The valve of the injector is combined with an index for showing to what extent the injector is open, and consequently to what degree the gas is being carburetted. Other means can be employed for drawing gas from the main, carburetting it, and again returning to the main. In all cases the hydrocarbon is volatilised.—F. W. T. K.

Improvements in Apparatus for Use in the Photometric Examination of Gases. W. Foster, London. Eng. Pat. 2571, February 19, 1890. 6d.

The gas enters a vertical tap or cock, the plug of which is fixed. A passage for the gas is made along the longitudinal axis of the plug, and this passage terminates laterally. A mass of metal carrying a number of arms can be rotated on this plug so that the passage in each arm can be successively brought into communication with the lateral

opening. When this is the case the particular arm lies in the direction of the photometer bar. The arms can be provided with different burners. When a flat flame burner is used, it is inserted into a special kind of tap at the end of the arm by means of which the supply of gas to the burner does not vary in quantity or pressure in whatever position the flame be viewed.

Two modifications of the apparatus are also given.

—F. W. T. K.

Improvements in Apparatus for the Production of Lighting Gas. H. L. Müller and W. Adkins, Birmingham. Eng. Pat. 4197, March 18, 1890. 8d.

This is an invention for charging gas machines using gasoline, whereby the same may be done continuously and the pressure be regulated. The arrangement is intended primarily for the "Alpha" apparatus, and consists of a rectangular pillar-shaped chamber which is partitioned off transversely by shelves which form a series of obstructing trays. Gasoline can be charged in at the top and flow as required into the gas machine at a uniform pressure.

Two sheets of drawings accompany the specification.

—D. A. S.

Improvements in or connected with Valves for Hot Gases. J. von Langer and L. Cooper, Leeds. Eng. Pat. 4225 March 18, 1890. 6d.

THE principal object of this invention is to provide a valve suitable for controlling the flow of hot gases or air. The valve is a hollow disc or plate, preferably circular, and is provided with a hollow flange adapted to dip into an annular cup containing a suitable liquid or solid packing material, and is mounted on a hollow vertical spindle (or spindles) guided by stuffing boxes, and is enclosed in a cast-iron casing. The spindle forms a continuous passage through the interior of the valve, and supplies it with cooling liquid, which is admitted through a flexible pipe attached to the lower end of the spindle, and is discharged through a similar pipe at the upper end.—E. S.

Improvements in Apparatus connected with the Manufacture of Gas. J. A. Kelman, London. Eng. Pat. 4324, March 19, 1890. 8d.

A WASHER or scrubber of square or rectangular shape is described, which is provided with a series of partitions mounted with short tubes, each tube having a dome shield provided with tangential vanes for breaking up the gas as it issues from the dome. A special condenser is also provided. This arrangement is illustrated by drawings.

—D. A. S.

Improvements in Furnaces to Promote Combustion. T. Norman and H. T. Simpson, Sheffield. Eng. Pat. 7886, May 22, 1890. 6d.

ONE or more air inlet pipes or conduits are carried vertically through the brickwork of a furnace to the bridge, pass horizontally through the bridge and terminate under the bridge in an air chamber which communicates with the back of the fire-box by upwardly inclined slits opening a little below the ends of the firebars. A steam jet forces air into the open external end of the conduit, and the mixture of air and steam is thus superheated in its passage through the conduit and firebridge before reaching the fuel.—S. B. A. A.

Improvements in Furnaces. L. C. Cohen and E. Hermann, Paris, France. Eng. Pat. 10,398, July 5, 1890. 6d.

THIS invention refers to improvements in furnaces previously patented.

The mouth of the furnace is so constructed that the rotary lower jaw is either in the form of a sector with its fulcrum at the lower end, or of highly curved form with its fulcrum at the upper end, so that the movement of the jaw presses the fuel into the main grate, and causes fresh

fuel to fall into the space made by the movement of the jaw. The slide grate is also altered so that the ashes fall through at the rear and combustion cannot go on in the front.

There are two sheets of drawings in the specification illustrating this.—D. A. S.

Improvements in Methods of Producing Combustible Gases for Heating and Lighting Purposes, and in Apparatus therefor. B. H. Thwaite, Liverpool. Eng. Pat. 13,574, August 29, 1890. 11d.

By means of specially-contrived valves, water-gas and generator-gas are made in the same producer so as to obtain a gas of fixed and uniform quality, which is afterwards invested with highly thermic and luminous qualities by the injection of oil or liquid hydrocarbons into and over the fuel. A pair of generating vessels are used; the gases from the first vessel are aspired to the second vessel through a connecting flue, and pass descensionally through the latter. To enrich the gas, liquid hydrocarbons or oil are injected preferably under high pressures, which may be directed either into the producer in which the descensional flow of gas is taking place, so that the volatilised gas may pass directly into the mains without decomposition of hydrocarbons, or may be directed into the ascending flow of gas, and fixed or rendered permanent during its passage through the fuel. There is an automatic arrangement for solid fuel feeding, and special valvular and aspiratory arrangements which cannot well be explained without reference to the drawings accompanying the specification, of which there are four sheets.—D. A. S.

Improvements in and Relating to Apparatus for Withdrawing Coke from Ovens and for similar Purposes. W. R. Lake, London. From N. O. Goldsmith, Cincinnati, U.S.A. Eng. Pat. 14,968, September 22, 1890. 11d.

THE invention relates to a new and improved device for drawing coke out of ovens. It comprises a driving device operated by an engine, preferably mounted upon a car which can be run to and fro in front of the oven, having an oscillating table, upon which is mounted the guides for the reciprocating arm carrying the pulling claws, with suitable mechanism for stopping, starting, tilting, and swinging the reciprocating claw arm in a horizontal and in vertical planes, all of which is done with power furnished by the boiler.

The apparatus cannot be described without reference to the drawings accompanying the specification.—F. W. T. K.

Coal-Gas Generating Apparatus. J. J. Thomas, Pennsylvania, U.S.A. Eng. Pat. 17,000, October 24, 1890. 8d.

THIS is an improved method of connecting two series of inclined (30°) retorts by having two saddle pipes and a connecting chamber with a valve located between the receiving chambers of each series so that the gas from either side may be mixed as desired with the gas of the other side before reaching the liquid seal in the hydraulic main. There is also a special travelling car for charging with a separate pocket for each retort. The retorts are constructed with contracted discharge ends. Each retort is 26 inches wide at the receiving end, and contracts to 20 inches. The contraction at the lower end causes the coals to be evenly distributed over the bottom of the retort. The gas from each series passes up through the receiving chamber and saddle pipe to the hydraulic main. When one of the series of retorts has run two hours the bottom lids are opened and the coke discharged, and the retort refilled as before. The valve being opened the hot gases rising from the retorts running more than two hours will pass and mix with the gas from those last charged. Thus the rich cold gas from fresh coal would be heated by the poor hot gas from the partly distilled coal and the mixed gases will pass the liquid seal as a rich and more permanent gas than if they had passed singly.—D. A. S.

An Improved Compound for Treating Fuel. H. H. Lake, London. From The Standard Coal and Fuel Co., Boston, U.S.A. Eng. Pat. 17,466, October 31, 1890. 4d.

A MIXTURE of saltpetre and sal-ammoniac in the proportion of 75 parts by weight of the former to 25 parts of the latter, forms a non deliquescent easily transportable mass which may be dissolved in water when required and the solution sprinkled over coal or other fuel.

The saltpetre provides oxygen for the thorough combustion of the fuel whilst the sal-ammoniac moderates the reaction and tends to hold back the smoke until thoroughly consumed.—S. B. A. A.

An Improved Compound for Treating Fuel. H. H. Lake, London. From The Standard Coal and Fuel Co., Boston, U.S.A. Eng. Pat. 17,470, October 31, 1890. 4d.

A MIXTURE of 37 parts by weight of saltpetre and 63 parts of Glauber's salt is claimed for the same properties and purposes as the mixture in the preceding specification.

—S. B. A. A.

An Improved Compound for Treating Fuel. H. H. Lake, London. From The Standard Coal and Fuel Co., Boston, Eng. Pat. 17,484, October 31, 1890. 4d.

A MIXTURE of 33 parts by weight of saltpetre and 67 parts of common salt is claimed for the same properties and purposes as the preceding mixtures.—S. B. A. A.

Improvements in Furnaces. H. H. Lake, London. From R. L. Walker, Boston, U.S.A. Eng. Pat. 17,727, November 4, 1890. 6d.

IN the improved furnaces the grate is made in two sections, the hinder and smaller of which is a rocking grate, and a deflector is arranged so as to direct the products of combustion of the fuel on the front section of the grate over the bright fire maintained on the movable grate by sufficient agitation. The products of combustion are in this way completely and economically consumed. In another modification the ash-pit is in addition divided into two chambers corresponding with the two sections of the grate and the rear chamber is provided with an air blast.

—S. B. A. A.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

Alexeev's Apparatus for the Treatment of Naphtha Tar and Naphtha Residues. Proc. Russ. Techn. Soc. 23, 24—28, and 24, 1—13.

THE principle of this apparatus being that the light hydrocarbons evolved in the course of distillation are forced back into the boiler and mixed with the crude material, it is particularly useful for decomposition of the heavy naphtha constituents, hitherto used merely as fuel, into lamp oil and

Fig. 1.

Fig. 3.

Fig. 2.

APPARATUS FOR THE TREATMENT OF NAPHTHA PRODUCTS.

vaselin. In Fig. 2, a front section of the apparatus, A is a boiler continually fed by naphtha tar or residues through the pipe *s* and heated from below. The pipe *a* leads vapour and gases from the boiler into the first condenser B, surrounded by a chamber G, and heated from the main hearth P, through heating flues *p p*. There are seven such condensers (of which only four are shown) B, C, D, E, &c., and seven corresponding chambers G, H, I, K, &c., connected by pipes *a, b, c, d, &c.* The last chamber is connected by a pipe *e*, with a final condenser and coil F, which ends in a branching pipe *g*; here, while the condensed liquid is flowing through the pipe *h* into the receiver R, the still gaseous hydrocarbons are sucked up the pipe *i* by an air pump V, and are subsequently forced through the pipe *k'* into the boiler A, where the perforated end of the pipe *k* is lying along the bottom, as in Fig. 1, which represents a section of a simpler apparatus with a single condenser. The farther the chamber is from the hearth the lower is its temperature and the lighter is the product condensing in it. Fig. 3 is a section of the chamber I surrounding the condenser D, with flues *m* (for increasing the condensing surface), and a discharging pipe *l*; *p* is the heating flue with a damper *r*.

The difference of temperature between the extreme points of the apparatus being about 280° (from 360° down to 80°), the various products of naphtha from the heaviest vasesin to the lightest sorts of "benzoline" are condensed in the intermediate condensers.

This apparatus is adopted in several naphtha works in Russia, and gives very satisfactory results. For instance, 5½ tons of naphtha tar, sp. gr. 0·927, has given after eight days of distillation 45 per cent. of crude vasesin and 25 per cent. of crude kerosin, or generally 35—40 per cent. of pure vasesin, sp. gr. 0·875—0·904, melting point 15°—35° C., and 15—20 per cent. of pure kerosin, sp. gr. 0·800, flashing point 34·3° C.

On the other hand 7½ tons of naphtha residues, sp. gr. 0·912 (at 17·5° C.) have given at the first distillation only 40 per cent. of kerosin, but when the heavier products had been repeatedly poured back into the boiler the whole 70 per cent. of pure kerosin were obtained, the additional 30 per cent. of kerosin being the result of decomposition of the heavier hydrocarbons under the condition of the apparatus. It works very quietly, requiring no special attention, and consumes about 16 pounds of liquid fuel for each 100 pounds of naphtha residues (the actual amount of the repeatedly distilled material being 300 pounds).

Until recently the apparatus of this system was considered impractical in Baku on account of the very low price of crude naphtha and a comparatively good and constant demand for residues for fuel. But the price of naphtha having begun to rise owing to some apprehension felt in Russia of an approaching decrease of the natural sources of the mineral oil, the former wasteful method of disposing of naphtha appears now to be dangerous, and the use of Alexeev's apparatus is recommended in order to increase the percentage of the most useful and valuable constituent (kerosin) obtained from crude naphtha from 35 per cent. (as hitherto) to 70 per cent., as it ought to be.—N. W. T.

Petroleum Wealth of Russia. J. Soc. Arts, 1891, 39, 275—277.

M. B. PRILEJAJEV, writing in the *Economiste Russe*, says that the development which from year to year is seen in the production of mineral oil in Russia, the increased exports abroad and the competition on foreign markets with American products, and, finally, the fears that have recently been expressed as to the probability of an approaching exhaustion of the sources of petroleum in the Caucasus, invest with a particular interest this important branch of Russian industry. The following is a summary of the progress effected, and the present condition of the petroleum trade. The extraction of naphtha is confined almost exclusively to the Caucasus, in the peninsula of Apcheroo, and principally in the environs of Baku. The existence of petroleum in the Caucasian soil was known at a very early period, and when these districts were still under Persian

rule, the Government made concessions to private individuals of the right of working the petroleum beds. After the annexation of Baku to Russia this industry was at first a monopoly, which brought into the treasury, from 1821 to 1872, an annual revenue of 87,000 roubles. After the suppression of this monopoly in 1872 an excise duty was imposed which was removed in 1877, and had yielded a total sum of 1,218,739 roubles. The yield from this source to the Imperial Exchequer in 1888 was nearly 7,000,000 roubles, and in 1889 over 9,000,000. From 1832 to 1862 the production of naphtha in the Caucasus was confined within narrow limits. During this period it varied from 255,500 pounds to 358,300 pounds annually (the pound is equivalent to 36 lbs. avoirdupois). From 1863 to 1868 it rose to between 538,900 and 998,900 pounds, and continued to rise until it amounted to 1,685,229 pounds in 1869, the year from which its enormous development dates. In 1870, the production amounted to 1,701,465 pounds; in 1875, to 6,285,728; in 1880, to 20,736,949; in 1885, to 115,000,000; and, in 1889, to 206,897,100 pounds. The environs of Baku supplied about 99 per cent. of the Caucasian production; in round numbers they yielded 165,000,000 pounds in 1887; 190,000,000 pounds in 1888; and 205,000,000 in 1889. The producing districts are situated at a certain distance from the town, on the plateaux of Balakhani, Sabountehi, and Sourakhani towards the north-east, and in the Bibi-Eibat fields which are to the south-east of Baku. In the Baku basin there were 216 wells in working in 1887, and 239 in 1888. The quantity of naphtha carried from the wells to the distilleries amounted to 186,220,470 pounds in 1889, and from January 1st to August 1st of 1890, it amounted to 138,732,688 pounds (against 99,930,712 pounds for the corresponding period of the preceding year). Professor Mendelejev estimates the daily production of the Baku district as follows:—In 1886, 328,890 pounds; in 1887, 415,000 pounds; and in 1888, 503,120 pounds. The Balakhani and Sabountehi fields are the most important. In the former there were 216 wells, in 1885, and in the latter 128. In 1887, the number of wells in both districts in full working amounted to 201, with a product of 153,246,672 pounds; and in 1888 they amounted to 227, giving a yield of 176,332,226 pounds. The average annual yield for each well was 762,421 pounds in 1887, and 776,794 pounds in 1888, an increase for the latter year of 2 per cent. The principal companies engaged in the extraction of petroleum are the Nobel, Caspian, Baku, Caspian and Black Sea, Schibaiev Mirzoev, Dembo and Cohan, and Zaturon and Arafelov Companies at Balakhani, Sabountehi, Tagaiev, and Sarkisov, and the Djakeli Companies, at Bibi-Eibat. The petroleum extracted from the wells is carried by pipes to the large stations or reservoirs, and thence distributed in the same manner to the works. This system was inaugurated in 1877. The quantity of raw petroleum delivered to the works by the Baku Companies amounted to 153,122,049 pounds in 1888, 186,220,476 pounds in 1889; and 192,044,202 pounds during the period comprised between the 1st January and the 1st November 1890. The distilleries are, for the most part, established at Baku, where they form a special district, which is known as the "black town." In this district there were 145 distilleries in 1887, which treated nearly 142,000,000 pounds of naphtha, and produced 38,000,000 pounds of refined petroleum (kerosene), 1,800,000 pounds of lubricating oil, and 40,000,000 pounds of residues, besides a considerable quantity of benzine, vaseline, and products of secondary importance. In 1889 the number of distilleries was 147, and their total product amounted to 181,590,232 pounds, of which 62,000,000 were light oils, 1,000,000 heavy oils, and 113,000,000 residues. Independently of the Baku basin, naphtha wells are found in other regions of the Empire. In the environs of Tiflis naphtha is found in the neighbourhood of Signakh, and at Naftlough. In 1887 there were 85 wells, which yielded 28,660 pounds of naphtha. In 1889 the Signakh wells alone furnished 55,296 pounds, that is more than 17,000 pounds more than the preceding year. In the Government of Elisasetpol the production was only 2,000 pounds in 1888, and 3,000 pounds in 1889; in Daghestan it was 3,350 pounds in 1888, and 3,935 in 1889; in the province of Terék, 161,442 pounds in 1888, and 275,721 pounds in 1889. The wells of the province of

Kouban are of greater importance. The following will show the distribution by districts of the petroleum refineries and their relative production in 1889:—Transcaucasia 148 refineries, with a production of 158,259,869 pounds; St. Petersburg and Moscow, 35, and 1,515,559 pounds; Central regions, 8, and 1,480,208 pounds; Southern, 6, and 944,689 pounds; Western, 2, and 324,215 pounds; Baltic provinces, 1, and 317,127 pounds; Northern, 1, and 15,719 pounds; South-western, 1, and 1,799 pounds; and Poland, 1, with a product of 511 pounds, making in the aggregate 203 refineries, with a yield of 162,859,956 pounds. The working of petroleum at Baku is placed under the direction of a committee of experts, established in 1856. The greater part of the petroleum extracted is consumed in the interior of the Empire. The petroleum is carried from Baku by the Caspian Sea, then by the Volga to Tsarit-syn. From this place a certain quantity goes up the river, but the greater part is carried by rail, in tank-waggons, to all parts of European Russia. The Nobel Company owns the largest amount of material for the transport of petroleum; in 1889 their vessels represented a value of nearly 6,000,000 of roubles, and their tank-waggons 3,000; the waggons belonging to the Caspian and Black Sea Company represented a value of 418,773 roubles. The Naphtha Company owns 2,310 tank-waggons, the Schibaiev 305, and the Caspian Company 200. These companies also own reservoirs in the principal cities of the Empire. Petroleum intended for foreign markets is shipped chiefly from the port of Batoum. The exports keep pace with the development of the petroleum industry. The importance of lighting oils in this export is accentuated from year to year. In 1883 refined petroleum only represented 41 per cent. of the total exports; the following years the proportion amounted respectively to 57 per cent., 67 per cent., 61 per cent., 62 per cent., 78 per cent., to attain the figure of 84 per cent. in 1890. In the year 1889 over 6,000,000 pounds of lighting oils and benzine were exported from Russia to the United Kingdom; 4,000,000 to Austria; 3,000,000 to Germany; 2,000,000 to Italy; 2,000,000 to Belgium; and smaller quantities to Holland, Roumania, Spain, Denmark, Sweden, Norway, Greece, France, &c. Turkey took in the same year 7,000,000 pounds; East Indies, 5,000,000; China over 1,000,000; Persia, 336,000; and Japan 330,000 pounds of lighting oils and benzine. In 1888, 77 per cent. of the total exports were effected *via* Batoum, and in 1889, 80 per cent. M. Prilejaiev concludes by quoting the opinion of Professor Mendeleef to the effect that there is no indication of an approaching failure of the petroleum supply of the Baku basin, leaving out of the question the other districts of Russia which still await the development of their naphtha wealth.

PATENT.

Improvements in Lubricating or Treating Fibrous Materials in Process of Manufacture. R. Hamilton, Trinity, and J. C. Hamilton, Linlithgow. Eng. Pat. 16,111, October 11, 1890. 4d.

See under V., page 251.

IV.—COLOURING MATTERS AND DYES.

Studies on the Constitution of Tri-Derivatives of Naphthalene, No. 9. Andersen's β -Naphthylamine-disulphonic Acid. Henry E. Armstrong and W. P. Wynne. Proc. Chem. Soc. 1891 (93), 27—28.

According to Schultz (this Journal, 1890, 282) naphthalene-1:3'-disulphonic acid on nitration yields a mixture of several nitronaphthalenedisulphonic acids. The chief product on reduction gives the so-called α -naphthylamine-disulphonic acid [$\text{NH}_2 \cdot \text{SO}_2\text{H} \cdot \text{SO}_2\text{H} = 1' : 3' : \text{r}$. Armstrong and Wynne (this Journal, 1890, 283)] of the

Germ. Pat. 45,776. Of the other acids, the production of which has also been noted by Bernthsen (this Journal, 1890, 1121), one yields on reduction, according to Schultz, a β -naphthylamine-disulphonic acid. As this was the first instance in which the formation of a β -nitro-acid by the nitration of a naphthalenesulphonic acid had been observed, the attention of the authors was directed to the determination of its constitution, and a supply of the material remaining after the separation of the greater part of the ϵ -acid, was obtained for investigation. After separation from the associated acids, and comparison with a specimen of the pure Andersen acid received from Schultz, the amido-acid was analysed by the hydrazine and Sandmeyer methods. When reduced by the hydrazine method, it gave naphthalene-1:3'-disulphonic acid, which was characterised by means of its chloride, $\text{C}_{10}\text{H}_7(\text{SO}_2\text{Cl})_2$, melting at 127° , and the derived 1:3'-dichloronaphthalene melting at 48° . On treatment by the Sandmeyer process, it was converted into a chloronaphthalenedisulphonic acid, the chloride of which, $\text{C}_{10}\text{H}_6\text{Cl}(\text{SO}_2\text{Cl})_2$, crystallised from benzene in radiate groups of flat needles melting at 174° , and on distillation with PCl_5 yielded 1:3:3'-trichloronaphthalene melting at $80\cdot5^\circ$. This acid, consequently, was identical with that obtained by the authors by sulphonating 2:2'- β -chloronaphthalenesulphonic with 20 per cent. anhydrous sulphuric acid (this Journal 1890, 801). As a further proof of the identity of the two compounds, the chloronaphthalenedisulphonic chloride derived from the Andersen acid was hydrolysed by heating with dilute sulphuric acid at 250° — 270° for several hours, with the result that β -chloronaphthalene melting at $59\cdot5^\circ$ was obtained. From these results it follows that the Andersen acid is a β -naphthylamine-disulphonic acid of the constitution—

PATENTS.

Improvements in and relating to the Manufacture of Colouring Matters. H. H. Lake, London. From A. Leonhardt and Co., Mülheim-on-the-Rhine, Germany. Eng. Pat. 4387, March 29, 1886. Amended June 4, 1890. 6d.

A FURTHER amendment to the original patent (see this Journal, 1887, 507; 1888, 319; and 1890, 608), relating to the employment of fuming sulphuric acid only for sulphonating and disclaiming the combination of diazotised diamidostilbene with *o*- and *p*-phenylene diamine, *o*- and *p*-tolylene diamine, and also with the following substances: 1. The homologues of aniline, with the exception of toluidine. 2. The homologues of phenol, with the exception of cresol. 3. The so-called β -naphthylamine- α -sulphonic acid. 4. That disulphonic acid of α -naphthol which, on treatment with nitric acid, yields binitronaphthol. There are, in addition to these corrections, some clerical amendments.—T. A. L.

Production of Brown Dyes or Colouring Matters. T. R. Shillito, London. From J. R. Geigy and Co., Basle, Switzerland. Eng. Pat. 1688, January 31, 1890. 4d.

A PROCESS for obtaining brown colouring matters for cotton by combining diazotised naphthylamine, amidoazobenzene or amidoazotoluene sulphonic acid with *m*-diamines, and further combining these compounds with diazotised primuline (polychromine). The following example shows the method of carrying out the invention. 28 kilos. of sodium naphthylate, dissolved in water and mixed with 30 kilos. of hydrochloric acid, are diazotised by the addition of 8 kilos. of sodium nitrite. This diazo solution is then poured into a solution of 12.5 kilos. of *m*-phenylene diamine, or the corresponding quantity of *m*-tolylene diamine and 20 kilos. of caustic soda. After standing 24 hours a solution is added, containing 55 kilos. of primu-

line diazotised with 3.5 kilos. of hydrochloric acid and 8 kilos. of sodium nitrite. The reaction is complete in about 24 hours, when the liquor is boiled and the dyestuff precipitated with salt. It forms a brown powder easily soluble in water and dyes unmordanted cotton from a neutral or slightly alkaline bath.—T. A. L.

Improvements in the Manufacture of Fast Dyestuffs for Printing and Dyeing. B. Willeox, London. From the "Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 3303, March 1, 1890. 6d.

AN extension of Eng. Pat. 8299 of 1889 (this Journal, 1890, 608; and 1891, 132), and of Eng. Pat. 1828 of 1890 (this Journal, 1891, 132). The diazo compounds of certain amidocarboxylic acids are combined with α -naphthylamine, or with α -amido- β -naphthol ether, and the resulting amido-azo-compounds are diazotised and combined with the amido-naphthol sulphonic acids G or R (obtained according to Ger. Pat. 3229) in an acetic acid or alkaline solution. The colouring matters obtained dye wool mordanted with chromium salts deep blue-black shades.—T. A. L.

Improvements in the Manufacture of Mordant Dyeing Azo Colouring Matters of the Triphenylmethane Group. B. Willeox, London. From the "Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 3398, March 4, 1890. 6d.

THE *m*- and *p*-amidotetra-substituted diamidotriphenyl methanes can, according to this invention, be diazotised and, after combination with, preferably, phenol carboxylic acids or certain dihydroxynaphthalenes, yield azo bodies which, on oxidation, form a new group of triphenylmethane derivatives termed azotriphenylmethane dyes. The process can be varied (1) by diazotising the oxidised *m*- or *p*-amido-tetra substituted diamidotriphenyl methanes and combining the diazo-compound with a phenol, naphthol, or their carboxylic acids or with dihydroxynaphthalene; (2) by oxidising the diazotised *m*- or *p*-amido-tetra substituted diamidotriphenyl methanes, and combining the diazo-compounds with the substances enumerated above. The production of a blue mordant colouring matter is described as follows: 34.5 kilos. of *p*-amido-tetra-methyl-diamido-triphenyl methane are dissolved in 200 litres of water and 33 kilos. of 33 per cent. hydrochloric acid, and after cooling to 0° C., added slowly to a solution of 7 kilos. of sodium nitrite. The diazo-solution thus obtained is added to 20 kilos. of hydroxynaphthoic acid dissolved in 120 kilos. of 33 per cent. caustic soda lye. The brown precipitate is filtered off, dried, dissolved in 200 litres of acetic acid, and oxidised with 84 kilos. of peroxide of lead paste (containing 28 per cent.). The whole is then gently heated, and the lead precipitated by 20 kilos. of 50 per cent. sulphuric acid. After filtering, the colouring matter is precipitated on dilution with water, the precipitation being completed by the addition of salt. It is employed as a paste, and dyes wool mordanted with chromium blue.—T. A. L.

Improvements in the Production of Grey Colouring Matters. O. Imray, London. From the "Farbwerke vormals Meister, Lucius und Brüning," Höchst-on-the-Maine, Germany. Eng. Pat. 4577, March 24, 1890. 6d.

NITROSODIETHYLANILINE hydrochloride reacts in an alcoholic or acetic acid solution with β -naphthol sodium sulphionate (Schäffer) at the temperature of the water-bath, forming new colouring matters. The condensation can also take place in an aqueous solution in presence of zinc chloride at 70°–80° C. The colouring matters dye wool grey to black, and the shades are said to be fast to light.—T. A. L.

Production of Grey Basic Colouring Matters by the Action of Hydrochlorate of Nitrosodimethylaniline or Hydrochlorate of Nitrosodiethylaniline upon 1.5 Dioxynaphthalin and upon 1.2 Tetraoxydinaphthyl. O. Imray, London. From the "Farbwerke vormals Meister, Lucius, und Brüning," Höchst-on-the-Maine, Germany. Eng. Pat. 5777, April 16, 1890. 4d.

THE colouring matters which dye cotton mordanted with tannin grey are obtained by heating to about 50° C. 16 kilos. of (1.4') dihydroxynaphthalene or (1.2) tetra-hydroxydinaphthyl with 18.6 kilos. of nitrosodimethylaniline hydrochloride, and about 100 kilos. of alcohol, until the nitrosodimethylaniline has completely disappeared. The product is then poured into water, and the colouring matter precipitated by the addition of salt. After filtering and washing, it may be used for dyeing.—T. A. L.

Production of Black Colouring Matters from Amidoflavopurpurine and Amido-anthrapurpurine. O. Imray, London. From the "Farbwerke vormals Meister, Lucius und Brüning," Höchst-on-the-Maine, Germany. Eng. Pat. 5780, April 16, 1890. 6d.

COLORING matters of the quinoline series are obtained by applying Skrap's synthesis to amidoflavopurpurine (obtained from β -nitroflavopurpurine) and to amido-anthrapurpurine (from β -nitro-anthrapurpurine). Two kilos. of amidoflavopurpurine, $C_{14}H_7O_3NH_2$, are dissolved in 14 kilos. of sulphuric acid of 66° B., and 1 kilo. of glycerol and 1 kilo. of nitrobenzene are afterwards added. The mixture is then slowly heated to 110° C. and kept at this temperature for eight hours. The melt is then decomposed by water, and the quinoline separated by means of sodium bisulphite, with which it forms a soluble compound. The base is precipitated from this solution by the addition of salt or sulphuric acid, and can be used directly as a colouring matter or mixed with bisulphite in solution for dyeing wool or printing on cotton, giving grey to black shades.—T. A. L.

Improvements in the Manufacture and Production of Substantive Colouring Matters. J. Y. Johnson. From the "Badische Anilin und Soda Fabrik," Ludwigshafen-on-the-Rhine, Germany. Eng. Pat. 6874, May 3, 1890. 6d.

BLUE colouring matters which dye cotton without a mordant are obtained by combining diazotised benzidine, tolidine, diamidostilbene, or dianisidine with (1.1') dihydroxynaphthalene, preferably in an acetic acid solution.—T. A. L.

The Vegetable Fibres of Trinidad. J. Soc. Arts, 1891, 325–327.

THE United States Consul in Trinidad has recently forwarded to his Government a report upon the vegetable fibres of that island, and gives a description of some of the most important of them. The *maholtine* is a plant

which grows wild in large quantities. It is easily cultivated, by simply cutting down bushes and burning them, and scattering the seeds of the plant. One acre of good ground will produce about 5,000 lb. of stalk; and this stalk, reduced to fibre, will make about 800 lb. The stalk grows from 8 to 12 ft., the skin or bark of which is stripped off, and steeped in cold water, eight or ten days after which the green watery substance is washed out, leaving a fibre 8 to 10 ft. long. The white *mahoe* (*Sterculia caribaea*), like the *maholtine*, grows wild, and may be cultivated in the same way, producing the same quality of fibre. The fibre is whiter and more silky than that of the *maholtine*, and is believed to be superior to it, although it has never been sent abroad to test its merits. A crop is reaped every seven months. The *gumbo* or *okra* (*Abelmoschus esculentus*) is another stalk fibre, the plant growing 6 to 8 ft. high, and producing a fibre about the same length. Cultivated on good soil, it will produce 4,000 lb. of stalks, yielding as much fibre to the pound as the *maholtine* or the white *mahoe*. The fibre of the *gumbo*, unlike those above mentioned, will not contain water, but throws it off like oil silk. A crop is harvested every seven months. The plantain (*Musa sapientum*) will produce from 5 to 6 lb. of fibre to each stalk. The stalks grow from 8 to 9 ft. high, and 800 of them may be produced on an acre of ground. The fibre is obtained by putting on two wooden rollers, and rolling and squeezing the stalks to crush the watery pores, then steeping it in water eight to ten days, and, finally, putting it under the same rolling process with heavier weights. The banana (*Musa paradisiaca*) grows 4 to 5 ft. high, produces 2 to 3 lb. of fibre to the stalk, and 800 stalks to the acre, and the crop is annual. Ramic or china grass grows very thickly, and when once planted sustains itself against other grass. After the first year it can be cut every six months. The stalk grows about 4 ft. high. It will produce an ounce of fibre to every square foot. The plant was imported into Trinidad from China for experimental purposes about three years ago, and has not yet assumed any commercial importance. The *mahoe bord du mer* (*Paritium tiliumum*) does not grow inland, but on the sea shore. It is a stalk fibre, but unlike the above it branches, and the branches also produce fibre. It grows 8 to 15 ft. high. Each tree will produce about $\frac{1}{2}$ lb. of fibre, and one acre can support 800 trees. Red *mahoe* (*Sterculia caribaea*) grows wild on any soil of the island, produces about 800 trees to the acre, grows 8 to 10 ft. high, and then branches. The stalk and branches are both used for fibre, which is used by the natives for making rope. The crop is annual. *Rucon*, or *amatto*, an Indian plant from South America, is a very strong fibre. One acre will support 800 stalks cultivated on fertile soil, and each stalk will produce about $\frac{1}{2}$ lb. of fibre. Black sage (*Cordia cylindrica*) is a small shrub about 6 ft. high, and produces a very strong fibre, used by the natives for making ropes. An acre of ground will support 1,600 plants, and they will give $\frac{1}{2}$ lb. of fibre to each plant. *Bois sang*, or blood wood, grows 25 ft. high, and branches out 8 to 10 ft. from the bottom. When tapped, the tree emits a fluid resembling blood, which produces a red stain. Both stem and branches produce fibre. About 600 trees may be produced to the acre, and each tree will produce 2 to 3 lb. of fibre, which is used for rope-making. The fibre varies from 4 to 6 ft. in length, is very tough, and would, it is said, make a superior twine for bagging. It is cut and planted every three years. *Balizer* (*Hibiscus*) is a wild plant, grows on cool soil, and its presence indicates superior land. The blades, which resemble the blades of the plantain, produce the fibre, but the blades grow from the roots of the bush like a pine-apple, and they are 6 to 10 ft. long. One acre will produce about 10,000 blades, and each blade will produce half an ounce of fibre. It is a coarse fibre, not so strong as the others mentioned, but is useful for door mats and similar purposes. *Cacao* (*Theobroma*) is cultivated for its valuable fruit, but the tree, which grows 15 or 20 ft. high, is trimmed annually in the spring of the year, and the branches of each tree thus trimmed will produce $\frac{1}{2}$ lb. of fibre, which varies from 3 to 5 ft. in length. It is strong, and is used as rope for making hammocks. *Bois l'oume* (*Guazuma ulmifolia*)

is a straight tree. At a distance of 8 or 10 ft. up the body of the tree, five or six branches shoot out in a circle round it, and from this point to the top of the tree, encircling branches shoot out at the distance of about one foot apart. The lowest circle of branches are the longest, and they shorten as they ascend the tree, causing the tree to assume the shape of a sugar loaf. Both the body and branches produce fibre. It is a straight brown fibre, and very strong, used generally for rope and twine making. Eight hundred trees may be produced to the acre, and after the third year will produce annually from 1 to 2 lb. of fibre to the tree. The *Agave Mexicana* grows 3 or 4 ft. high, and one acre will support 2,500 plants. After three years, each blade will produce half an ounce, or about half a pound to the plant. The crop may be reaped each succeeding year for from 12 to 16 years without replanting. The plant becomes dry and worthless as soon as it produces a flower, but it rarely produces the flower before 12 years, and usually not before 16 or 20 years. The plant grows wild on the island, but it is understood to have originally been brought from Mexico. The fibre is 3 to 4 ft. long, fine, strong, and it is said, would doubtless be good for textile purposes. The *Agave Americana*, or American aloë, grows higher than the *Agave Mexicana*. It varies in height from 4 to 5 ft., and the fibre is the same length. It grows abundantly, chiefly near the sea shore, and is understood to be a native of the island. The fibre is coarser than the Mexican agave, but about the same quantity can be produced to the acre. Of the pine-apple (*Ananassa sativa*) only the blade, which is about 2 ft. long, produces fibre. The fibre is strong and fine, and is believed to be well suited for textile manufactures. It is of finer texture than either the American or Mexican agave. *Agave rigida*, or sisal hemp, has lately been introduced into Trinidad. The blades alone, which grow about 2 $\frac{1}{2}$ to 3 ft. long, are used for fibre. Eight blades, it is said, give an ounce and a half of fibre, and the fibre obtained is about 3 ft. long, strong, coarse, and stiff, suitable it is believed for strong ropes and chair-bottoms. An acre will support 2,000 plants of about 16 blades each, and calculated to produce at each reaping 3 oz. of fibre to the plant. After three years a crop is reaped annually. Among the fibre-producing plants of Trinidad may be mentioned the *genome* (*Malachra*), *bois ceip* (*Oreodaphne cernua*); *gumbo mizse*, the piquine or wild pine-apple; the Spanish needle (*Yucca*); and the *Sanseria zeylanica*. Consul Peirce states, in conclusion, that he has been informed that there is no machine now in use in the colony which obtains the fibre without destroying the substance of the fibre ribs. The principal machine, if not the only one, now used in Trinidad and Tobago, is arranged for the operator to hold the blade of the plant in his hand, while the machine scrapes out the green and watery substance. The opinion has been expressed that if a machine could be introduced that would act somewhat on the principle of a cane-mill, in which the cane enters one side and comes out at the other thoroughly crushed and squeezed, a great advantage would be gained over the present practice.

Cultivation of Hemp in Smyrna. J. Soc. Arts, 39, 1891, 186-187.

In cultivating hemp in Smyrna, the United States Consul there says, that from one and a half to two bushels of seed are sown per acre. The fibre is long and tough, and of good yellow tinge; but, owing to the crude process of shedding, its good qualities are nearly ruined. The price of seed varies between 2s. 3d. and 2s. 7d. a bushel; and it generally contains from 12 to 15 per cent. of extraneous matter, chiefly sand. The height that the hemp usually grows is from six to seven feet and a half; in some cases so high, in fact, that Consul Emmet says a man can ride through his fields on horseback without being seen. Hemp is cultivated in almost every village or hamlet of Asia Minor, where an abundance of running water is to be found. The hemp fields are cultivated as near the water as possible, owing to the moisture required while growing, and the use made of the stream after the seed is gathered.

The ground is lightly ploughed, and sown broadcast with from one and a half to two bushels of seed per acre. It is then gone over with a heavily-weighted plank, drawn by oxen, to break the furrows and cover the seed. Nothing more is done to it. If the season be advantageous, and the water supply does not fail, by the receding of the stream, the yield will be good. The crop is cut and put in bundles, when the stalks turn yellow. The seed is gathered, and the sheaves of stalks are immersed in the stream near by, for the purpose of rotting the shell or reed containing the hemp fibre. When the cultivator thinks it sufficiently softened, the bundles are taken from the water, opened, and subjected to a heavy pounding with large mallets. After this, the fibre is extracted by hand, and put in shape for selling. Owing to the process of softening the stalks, or perhaps leaving them too long under water, the fibre darkens and partly rots when exposed to the air, which renders it unfit for foreign markets. It is consumed in the manufacture of coarse bagging and rope, for use in the interior. The hemp seed grown in Smyrna, and exported abroad, is of good quality, and is exported mainly to Germany, Austria, Holland, and the United States, for the extraction of oil. It is also used, to some extent, by the natives as an article of food. The seed is pounded in mortars, and made into a paste, and then fried. The Jews are particularly fond of it, and value it. The principal places in the vilayet of Smyrna where hemp and hemp seed are obtained are Odenish, Thyras, Mazli, and Honak Caireh.

PATENT.

Improvements in Lubricating or Treating Fibrous Materials in Process of Manufacture. R. Hamilton, Trinity, and J. C. Hamilton, Linlithgow. Eng. Pat. 16,144, October 11, 1890. 4d.

With a view to facilitate the processes of rope-making, spinning, weaving, &c., the fibrous material therein employed is lubricated with substances called by the patentee "fergolene." These are compounds consisting of sulphonic acids or their alkaline salts obtained as by-products in mineral oil refineries or from other sources where olefines are treated with sulphuric acid. The substances are preferably used in a neutral condition either alone or in combination with mineral or fatty oils.—K. E. M.

The Firing of Substantive Colours on Cotton. W. M. Gardner. Textile Manuf. 1890, 345.

ALTHOUGH but five or six years have elapsed since the introduction of the first Congo colour, now some 70—80 such are known. At first only reds and oranges existed, next came browns, and then the first blue azo colour in the group of benzidine colours. On account of the dullness of the shade new blues came in: benzo-azurin, sulphonazurin, diamine-blue. The present methods of fixing these colours are unsatisfactory; whilst the colours in many cases react quite differently, yet they are dyed in exactly the same manner. According to experiments made in the dyehouse of the Yorkshire College, Leeds, common salt should be added for the deeper shades, or a small quantity of soda or acetic acid may be used. The necessary amount of salt is so variable that each colour has its own peculiar quantity.

In the following table these quantities of salt are stated, as well as the action of dilute acids on the colours.

Colour.	Salt for 1 Litre Bath.	Action of	
		Dilute Acetic Acid.	Dilute Sulphuric Acid.

In the case of all substantive colours, whether they be red, yellow, or blue, it is best to dye in the hot bath, boiling for $\frac{1}{2}$ —1 hour.—T. L. B.

Kath or Pale Catechu. H. Warth. J. Soc. Arts, 39, 1891, 156—157.

THE Secretary of State for India has received from the author a memorandum, from which the following particulars are taken:—

"The kath of the North-West Provinces, which is used with pân, and the catechu of Burma, which is exported to Europe as a dyestuff, are both prepared from the wood of *Acacia catechu*. The kath is in its purest state chiefly catechin, a crystallising substance nearly insoluble in cold water. The catechu is chiefly catechu tannin, a substance soluble in cold water, and not crystallising, but some catechin is usually mixed up with it. The difference between kath and catechu is partly due to the methods of manufacture, partly to the difference in the trees.

"The trees in Burma differ from those of the North-West Provinces, and at each place there are two kinds of trees, Nos. 1 and 2, although of exactly the same species. Trees No. 2 have white spots in the wood, caused by a white substance stored up in cylindrical masses half a millimetre thick and 10 millimetres long. Trees No. 1 have no white spots. Trees with spots yield an extract richer in catechin; and both kinds of trees in the North-West Provinces yield more catechin than the corresponding kinds in Burma.

"I found the following proportions of catechin in the total extract:—

	Catechin.
	Per Cent.
Burma, No. 1	44
" No. 2 (spotted)	30
North-West Provinces, No. 1.....	36
" " No. 2 (spotted) ..	40

"The greatest amount of extract obtained from each kind of wood was as follows:—

	Extract.
	Per Cent.
Burma, No. 1	47
" No. 2 (spotted)	18
North-West Provinces, No. 1.....	44
" " No. 2 (spotted) ..	21

"The greatest amount of catechin obtainable from these woods is, accordingly, as follows:—

	Catechin.
	Per Cent.
Burma, No. 1	2
" No. 2 (spotted)	5
North-West Provinces, No. 1.....	5
" " No. 2 (spotted) ..	9

"Such a great proportion of catechin in the spotted wood of the North-West Provinces explains that kath manufacture is at home there. Moreover, the local kath makers are reported to refuse to unit all trees as unit which do not contain white spots, so that the trees No. 1 become wasted in the forests.

"I determined the catechin by direct separation, as follows:—About two ounces of the wood reduced to thin shavings were boiled with 20 times their weight of water for half an hour. The extract was separated from the wood by repeated settlement, and reduced in bulk on the water-bath until it just began to thicken, and contained, by estimate, 6 per cent. of catechin. It was then left in a cool place for five days for the separation of the catechin. Once the catechin had separated, the liquid could again be diluted with cold water for the purpose of filtering. The filtered and roughly-washed catechin was dried at ordinary temperature, and weighed in a thoroughly air-dry condition.

"The high degree of concentration, and the long standing are required because the catechin separates with difficulty out of an extract which contains so much catechu tannin. Once the bulk of the tanning is separated, the catechin may be dissolved in much more water, and it will separate immediately on cooling; but the catechin is at all times a delicate substance, which changes with water slowly into a soluble substance, and is thus lost. The drying of the moist catechin must take place at a low temperature, as heat at once destroys the microscopic crystals.

"The manufacture of kath, or raw catechin, is carried on in the forests with very primitive appliances. The filtering is done through layers of sand, and much sand becomes mixed up with the kath. The drying is performed in the open air.

"Contact with iron must be scrupulously avoided during the extraction of catechin. With catechu or cutch, contact with iron is of no consequence; and the reports mention iron cauldrons in use for the final boiling down of the cutch in Burma."

PATENTS.

Improvements relating to the Treatment of Dyewoods and their Extracts. M. G. Lindemann, Ottensen, Germany. Eng. Pat. 3788, March 10, 1890. 4d.

Dyewood extracts are to be treated with the manganates or permanganates of potassium or sodium, or with peroxide of hydrogen which is said to increase the tinctorial power of the solutions.—T. A. L.

Improvements in the Manufacture of Dyestuffs. S. Pitt, Sutton. From L. Casella & Co., Frankfort-on-the-Maine, Germany. Eng. Pat. 4904, March 28, 1890. 4d.

By heating together dimethylamine and fluorescein in an alcoholic solution at 140—160° C. a product is obtained which has the properties of a phenol and a weak base. This is known as dimethylrhodaminol and as hydrochloride dyes animal fibres and vegetable fibres mordanted with tannic acid and tartar emetic a fine red. If the temperature be raised to 180° C. another substance is obtained which is identical with tetramethylrhodamine. The same reaction takes place up to 210° C., but at 230° decomposition commences. In place of fluorescein its methyl or ethyl ethers may be used.—T. A. L.

Improvements in Printing or Stamping Inks. C. M. Higgins, Brooklyn, U.S.A. Eng. Pat. 15,857, October 7, 1890. 6d.

Oleic acid is claimed as a solvent for coal-tar dyes in the manufacture of inks suitable for type-writing, ticket-printing, &c., where a copyable ink which will not harden or dry on the inking device, is required. Oleic acid, too, may be mixed with such pigments as carbon, ultramarine, and Prussian blue, to furnish inks suitable for the purposes mentioned.

—E. B.

Improvements in Printing or Stamping Inks. C. M. Higgins, Brooklyn, U.S.A. Eng. Pat. 15,858, October 7, 1890. 6d.

INKS suitable for hand-stamps, type-writers, and small printing machines, are made by dissolving coal-tar dyes in essential oils or in mixtures of essential oils and oleic acid; thus, a violet ink is prepared by dissolving methyl violet in oil of cinnamon, oil of cloves, or oil of cassia (cinnamon leaf), the last-named oil being preferred for use with rubber stamps in which the inking-pad rests on the rubber, since it does not injure the rubber. A green ink is obtained by dissolving "green crystals" in oil of cloves. Blue inks are produced either by mixing the violet and green inks or by dissolving Chinese blue in oil of cloves. Carbon, carmine, and ultramarine blue may be incorporated with any of these inks.—E. B.

An Improved Process for the Extraction of the Tartrate of Lime contained in Lyes and other Tartarous Matters, and its Transformation into Cream of Tartar or into Tartaric Acid. A. Martignier, Montpellier, France. Eng. Pat. 20,078, December 13, 1889. 6d.

WHEN calcium tartrate is treated with a saturated solution of potassium sulphate in excess, neutral potassium tartrate and calcium sulphate are obtained.

This reaction is now applied for the extraction of the calcium tartrate contained in the neutralised lyes (lees), &c. The reaction takes place cold or hot, and after its termination the solution of neutral calcium tartrate is separated from the gypsum, decolourised by animal charcoal, and precipitated with an equivalent of sulphuric acid as potassium bitartrate (cream of tartar), half of the potassium sulphate being hereby regenerated.

This cream, or the original liquor, may be used for the manufacture of tartaric acid by first converting into calcium tartrate. This may be treated with sodium sulphate; the filtered and decolourised liquor containing neutral sodium tartrate and excess of sodium sulphate then treated with an equivalent quantity of sulphuric acid and potassium sulphate, potassium bitartrate being precipitated; or the lyes and tartars may be treated direct with a mixture of the sulphates of potassium and sodium. Neutral potassium tartrate is formed, the sodium sulphate assisting the reaction.—H. A.

Improvements in the Treatment or Preparation of Nitrate of Ammonium. "The Roburite Explosives Company, Limited," London. C. Roth, Charlottenburg, Germany, and W. J. Orsman, Gathurst. Eng. Pat. 20,104, December 13, 1889. 4d.

Improvements in the Manufacture of (Soda) Alum. F. M. Spence and D. D. Spence, Manchester. Eng. Pat. 448, January 10, 1890. 6d.

SALTCAKE (1 part) is dissolved by the aid of live steam in a boiling solution of 5 parts of aluminio-ferrie cake of 1·3 sp. gr. The solution is run into a leaden tank and allowed to settle for about 20 hours. The clear liquor is then drawn off and concentrated to about 1·45 sp. gr. by means of high-pressure steam. In using aluminium sulphate instead of aluminio-ferrie cake, the density of the concentrated liquor should not exceed 1·425 sp. gr. The clear liquor is run into shallow coolers, and occasionally agitated with wooden rakes. The cooling of the liquor is thus greatly promoted, and when the temperature is sufficiently low, the whole mass solidifies to a magma. This magma will remain unchanged if left to itself; occasional working up with wooden spades, &c., however, causes it to deposit crystals of soda-alum. These are separated from the mother-liquor, and may be washed with the mother-liquor of the second crystallisation, re-dissolved, and treated in the same way as the original liquor.

In evaporating the mother-liquor from the first crystals to 1·45 sp. gr., a further quantity of soda-alum will be deposited; the mother-liquor may also be utilised for the purification of sewage; or for the production of potash- or ammonium-alum. (See also this Journal, 1890, 1129.)

An Improved Compound for the Generation of Carbon Dioxide, and suitable for use in Gasogenes, Fire-Extinguishers, and similar Apparatus. H. Grimshaw, Manchester. Eng. Pat. 984, January 20, 1890. 4d.

THE compound consists of an admixture of sodium bicarbonate and sodium bisulphate in molecular proportions, either in the form of a dry powder or slightly damped and granulated by the aid of heat. Any other alkaline or alkaline-earthly carbonate or bicarbonate may be used, along with a suitable soluble bisulphate or biphosphate.

—H. A.

Improvements in the Manufacture of Soda and Potash. F. Ellershausen, Hebburn-on-Tyne. Eng. Pat. 1016, January 20 1890. 4d.

IN the usual way of manufacturing caustic soda, a dilute solution of black-ash is causticised with lime, concentrated and the residue fused to form solid caustic. The object of this invention is the saving of the large quantities of fuel necessary for boiling down such dilute liquors. Accordingly a strong solution of black-ash is mixed with iron peroxide to form a thick paste, the mass calcined, and the sodium ferrate so obtained lixiviated with sufficient warm water to form a strong solution of caustic soda. The iron peroxide is hereby converted into hydrate, which may be used over again either with vat-liquor alone, or in conjunction with the fished salts obtained in evaporating the caustic soda solution, or with sodium sulphide, as described in Eng. Pat. 1015 of 1890.—H. A.

Improvements in the Manufacture of Anhydrous Barium Oxides. H. H. Leigh, London. From T. de Brochocki, Paris, France. Eng. Pat. 1300, January 24, 1890. Amended September 25, 1890. 4d.

THE patentee now restricts his claim to the use of "carbon," the words ("coal dust") in the claim being deleted. (Compare this Journal, 1890, 510—511.)—H. A.

Improvements in the Method of Vapourising Solutions containing Nitrates of Manganese, and in the Means used for Decomposing the said Nitrates. G. Wischin, St. Petersburg, Russia. Eng. Pat. 1524, January 28, 1890. 8d.

Is the usual way of manufacturing chlorine from a mixture of nitric acid, manganese peroxide and manganese chloride (or hydrochloric acid), an acid solution of manganese nitrate is formed, from which manganese dioxide and nitric acid are regenerated by evaporating the solution to dryness and heating the residue, the manganese nitrate decomposing about 400°, manganese dioxide being left, while the nitrous fumes given off are condensed. The evaporation of the still-liquors presents great difficulties on account of the action of nitric acid on iron, and also formation of hard crusts of manganese dioxide on the bottom of the vessel.

It is proposed to overcome these difficulties by protecting the bottom of the evaporating vessel with a layer of granulated or powdered manganese dioxide or an equivalent; the vessel is kept hot, to avoid condensation of nitric acid on the sides; the liquor is fed in gradually, whilst the mass is kept in constant movement by means of a mechanical agitator, thus preventing the formation of crusts and also furthering the evaporation.

The apparatus may consist of a cylindrical cast-iron pan with flat bottom and outlet for continuous or intermittent delivery of recovered manganese. The flat top is provided with an outlet for nitric acid vapours, and with small

apertures for feeding in the liquor and in connexions by means of branch pipes with a liquor distributor. The wings of the agitator are close to the bottom and the luting of the agitator-shaft is done by a bell moving in a sand lute. The pan is set in a furnace and protected by a perforated arch. —H. A.

Improvements in or connected with Apparatus for the Manufacture of Sulphuric Acid. E. and T. Deplace, Aubervilliers, France. Eng. Pat. 5058, April 1, 1890. 8d.

THE improvements comprise (1) a modified burner for the better utilisation of the sulphur contained in the pyrites; (2) two Glover towers: A to concentrate the chamber acid and simultaneously to cool the burner-gases, C for the denitrification of the nitrous vitriol. The object of this arrangement is to prevent the decomposition of nitrous gases, owing to an excess of sulphurous acid gas and a high temperature. (3.) A dividing chamber E, allowing of a complete mixture of the gases and separation of the same into two distinct currents, which enter the chamber at F and G. (4.) A chamber H, forming on the inner and outer circumference a circle, or semicircle, an oval, spiral, polygon, &c., to ensure a proper mixing of the gases by the constant changes in the direction of the gases travelling through the chamber. A second circular chamber P, if desired, and a Gay-Lussac tower Q completes the system.

Fig. 3.

Fig. 2.

Fig. 1.

SULPHURIC ACID MANUFACTURE.

The pyrites burners are placed in a row, each burner being provided with five shelves R (instead of six). The gases from each kiln pass through openings *t* in a mutual collecting chamber T, extending over the whole length of the kilns. Parallel with this and connected to it runs a

dust chamber M, provided with short partitions N, which cause the gas to take a zigzag course.

The towers A and C are packed with natural acid-proof stone; the gases after leaving A pass through B and enter the second tower C on the top, passing from

the bottom into a collector D, containing a central partition; the gases are thus split up into two currents, each having to pass through a chamber E, packed with acid-proof stone or with parallel tubes, for further sub-division. Leaving the two opposite ends of the dividing chamber, the gases enter the lead chamber H. In order to equalise the pressure within the chamber the patentees "connect the roof or upper part of the chamber with the bottom at suitable intervals by means of distributing pipes I, which receive a portion of the high-pressure gases at the top of the chamber and conduct it along the outer or inner circumference down to the bottom." (Fig. 4.)—H. A.

Improvements in Obtaining Oxygen Gas from Atmospheric Air. A. Longsdon, London. From F. Salomon, Essen, Germany. Eng. Pat. 6553, April 29, 1890. 4d.

See under XX., page 270.

A New or Improved Continuous Method of Generating Carbonic Acid Gas from a Soluble Carbonate in Solution and an Acid in Solution, and in Apparatus connected therewith. J. McEwen, Manchester. Eng. Pat. 6758, May 2, 1890. 8d.

THE solutions of the carbonate and of vitriol are kept in cisterns provided with taps or valves to regulate the flow of the liquors into the generator. This vessel is fitted with a number of inclined shelves to retard or prolong the movement of the solution in the generator until the mixture is as "near neutralised as found practicable." The carbonic acid gas is delivered into a gas-holder, the height of which may automatically regulate the valves on the liquor-mains, and thus the outflow of the liquor. The spent liquor in the bottom part of the receiver may be kept in constant agitation by means of an Archimedian screw, and syphoned off as desired.

Two sheets of drawings accompany the specification.

—H. A.

Improvements in the Treatment of certain Minerals or Slag containing Phosphate of Lime for the Purpose of Obtaining the Latter in a concentrated Form with or without the Production of Alkali as a By-product, and in Apparatus therefor. J. Simpson, Liverpool. Eng. Pat. 12,670, August 13, 1890. 8d.

It is proposed to eliminate the carbonate or oxide of lime from phosphatic rock or slag of low percentage, and so to convert the slag into a richer and marketable article. The rock is first burnt in a furnace to convert the carbonate of lime into caustic lime (in the case of slag the lime is already present as oxide), then suspended in water and treated in a series of vessels with sulphuretted hydrogen under a pressure of at least 20 lb. per sq. in., until sulphuretted hydrogen begins to be evolved at the last vessel of the series. The lime should exist now in solution as sulphhydrate, which is drawn off, whilst the remaining concentrated phosphate is washed, run on a filter, and dried.

The calcium sulphhydrate liquor is decomposed in another series of vessels by means of carbonic acid, and the sulphuretted hydrogen so liberated used for treating a new quantity of phosphatic rock.

An alternative working consists in treating the calcium sulphhydrate liquor with a corresponding quantity of salt-cake, preferably under a pressure of 60–70 lb. of steam.

Hydrated calcium sulphate is precipitated, which, at this temperature, is insoluble in water. The sodium sulphhydrate solution so obtained, "is preferably concentrated by evaporation to the extent of about 40 per cent." then treated with carbonic acid, when sulphuretted hydrogen is given off and sodium bicarbonate precipitated. "Further concentrations are also necessary for the removal of the whole of the alkali as bicarbonate."—H. A.

Improved Process for Purifying Brines. H. J. Allison, London. From M. M. Monsanto, Hoboken, U.S.A. Eng. Pat. 14,544, September 16, 1890. 4d.

THE invention consists in precipitating lime, magnesia, iron, &c., from brine by adding to the brine tri-sodium phosphate (Na_3PO_4). Even when less tri-sodium phosphate is added than is sufficient to decompose the whole of the calcium sulphate present, it has the "unexplained property" of preventing the calcium sulphate forming a scale upon the evaporating vessel.—H. S. P.

Improvements in the Production of Sulphhydrate of Calcium to be used in the Manufacture of Alkali and Sulphuretted Hydrogen, and in Apparatus therefor. J. Leith, St. Helens. Eng. Pat. 15,648, October 3, 1890. 4d.

THE gases containing sulphuretted hydrogen which are given off under pressure from the carbonating plant of the Parnell and Simpson process (Eng. Pat. 381, 1885; this Journal, 1885, 498) are passed into a series of tanks containing a mixture of Leblanc alkali-waste (or other material containing sulphide of calcium) and water, thereby forming a solution of calcium sulphhydrate.

The sulphhydrate thus obtained is used in the still for liberating ammonia from the ammonium chloride produced in the carbonating plant, sulphuretted hydrogen and ammonium sulphide being thus evolved. The ammonium sulphide is absorbed by brine which is afterwards treated with carbonic acid in the alkali manufacture, whilst the sulphuretted hydrogen, after passing through a scrubber where any ammonia is removed by brine or by acid, is collected in a gas-holder for use as required.—H. S. P.

VIII.—GLASS, POTTERY, AND EARTHENWARE.

PATENT.

Improvements in Brick and Pottery Kilns. T. Fletcher, R. C. Brown, and W. Ure, Camerton. Eng. Pat. 3343, March 3, 1890. 6d.

By an arrangement of flues and dampers the products of combustion from any one of a series of kilns may be led as desired into any other of the kilns. With this arrangement the waste gases of a kiln nearly burnt off can be turned into a freshly lighted kiln, and so aid in consuming the smoke, economise fuel, and at the same time enable a better product to be produced by preventing discolouration.

—D. A. S.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

Hot Tests for Hydraulic Cements. M. Deval. Bull. Soc. d'Encouragement, 1890, 560–583.

H. LE CHATELIER has been deputed to examine and report upon a paper by the author on the use of hot water tests for cements and hydraulic limes. In the first place he reviews the causes that have led to the adoption of such tests in the following terms:—

It is at first sight strange that tests of this character should be used for a material which is rarely used under like conditions. In order to understand why this is, it is necessary to remember that cements, when actually incorporated in the work, are in a condition of continual alteration; they suffer gradual change from the moment of setting until they are destroyed. Their destruction under the attack of natural forces may be exceedingly slow, but is in any case inevitable. Such disintegrating agencies need

above all things time for their action to become perceptible, so that no successful attempt to gauge the quality of the cement by imitating the natural conditions to which it is subjected is possible in any reasonable period. Conceding that such imitation is impossible, it is futile to cavil about any one condition such as the temperature of the water. In laying down rules for testing cement, it is only requisite to seek to adopt a method of examination which ranges the cements tested as nearly as possible in their true order of merit, and the plan thus chosen may be wholly arbitrary. Considering that rise of temperature often aids chemical action, it is reasonable to strive to ascertain whether a short test at a high temperature may not give the same results as a long period test at the ordinary temperature. Especially, as has been already shown (this Journal, 1889, 514), is a hot water test useful in detecting latent tendencies to crack or blow owing to the presence of free lime, and it seems likely that further experiments in this direction will lead to useful results.

It should never be forgotten that there is at present only one way of determining whether the judgment passed on a cement by any system of testing is sound, and that consists in waiting half a century to see how the work stands—a method of limited utility. Failing an absolute criterion, the empirical rules based on the observations of the technical worker, which are commonly accepted, must be adopted, and the chemical composition, tensile strength, free from tendency to expand and crack ascertained in the usual way.

Selecting the most generally employed method of testing, Deval has compared the tensile strength of briquettes 5 sq. cm. in section made with a mixture of 1 part of cement to 3 of normal sand gauged with the minimum amount of water, presumably by hand, and broken after the elapse of 7 and 28 days, the hardening being allowed to proceed under water at 15° C. with that of those prepared in the same manner, but exposed to water at 80° C., and broken after 2 and 7 days. The use of the least possible quantity of water for gauging was adopted at the instance of cement makers, but though giving high results for a short time after setting, has the disadvantages of causing large discrepancies in the results, and of making the precise figures obtained dependent on the conscientiousness of the operator as well on the extent to which he is tired by previous work. Mere experimental errors are usually as high as 10 per cent. and may reach 100 per cent. in certain instances, and this fact must be remembered in considering results such as are given below.

Portland Cement.—The chief proximate constituents of Portland cement are (1), $\text{SiO}_2 \cdot 3 \text{CaO}$, the essentially cementitious ingredient; (2) $\text{Al}_2\text{O}_3 \cdot 3 \text{CaO}$, the substance mainly active during setting and contributing to some extent to the subsequent hardening; and (3) a fusible calcium silico-aluminate whose chief function is that of a flux during burning to promote the necessary chemical reactions. (For a fuller account of these bodies see H. Le Chatelier's work; this Journal, 1889, 567.) Besides these and sundry silicates which are tolerably inert, the only other constituent calling for notice is *free lime* which may result from the use of wrong proportions or imperfect mixing or burning, and is dangerous even in quantities less than 1 per cent. The first series of experiments was carried out with six samples of cements which are classified below according to their methods of manufacture.

(1.) Good finely ground cement of modern make. It gave the following results on analysis:—

	Per Cent.			
SiO_2	21.3			
Al_2O_3	7.8			
Fe_2O_3	2.4			
CaO	65.2	CaO	MgO	
MgO	1.4	SiO_2	Al_2O_3	2.33*
SO_3	0.7			
Water and loss	1.2			
	100.0			

It left a residue of 3 per cent. on a sieve with 900 meshes per sq. cm. and 18 per cent. on one of 500 meshes.

(2.) Coarsely ground cement of good quality, but of somewhat ancient date and partly aerated by long storage in the laboratory:—

	Per Cent.	
SiO_2	25.8	
Al_2O_3	8.4	
Fe_2O_3	2.5	
CaO	58.3	$\text{CaO} + \text{MgO}$
MgO	1.2	$\text{SiO}_2 + \text{Al}_2\text{O}_3 = 2.42^*$
SO_3	1.3	
Water and loss	14.5	
	100.0	

3 per cent. on 185 mesh sieve; 11 per cent. on 900; 35 per cent. on 5,000.

(3.) Quick-setting cement made by reducing the percentage of lime, and the consumption of fuel in order to compete with the natural Vassy cements.

	Per Cent.	
SiO_2	22.1	
Al_2O_3	8.6	
Fe_2O_3	2.5	$\text{CaO} + \text{MgO}$
CaO	63.4	$\text{SiO}_2 + \text{Al}_2\text{O}_3 = 2.60^*$
MgO	1.4	
SO_3	1.0	
Water and loss	1.0	
	100.0	

The three cements the composition which has just been given may be considered of good quality for their respective uses.

(4.) Cement made from clinker possessed of the property of disintegrating spontaneously while cooling, indicating the existence of a large proportion of inert material:—

	Per Cent.	
SiO_2	28.2	
Al_2O_3	8.1	
Fe_2O_3	2.6	
CaO	58.4	$\text{CaO} + \text{MgO}$
MgO	0.9	$\text{SiO}_2 + \text{Al}_2\text{O}_3 = 1.78^*$
SO_3	1.0	
Water and loss	10.8	
	100.0	

(5.) Underburnt cement obtained by grinding the underburnt clinker that is always present in larger or smaller quantity. Such cement contains free lime and slakes slowly on exposure to air.

	Per Cent.	
SiO_2	20.1	
Al_2O_3	7.7	
Fe_2O_3	2.2	$\text{CaO} + \text{MgO}$
CaO	65.0	$\text{SiO}_2 + \text{Al}_2\text{O}_3 = 2.93^*$
MgO	1.0	
SO_3	1.4	
Water and loss	2.6	
	100.0	

This particular sample is not only underburnt but high in lime, so high that it would be difficult to ensure perfect combination even by adequate burning.

(6.) A cement exceedingly high in lime made for experimental purposes. It is quite unfit for use even though properly burnt. Briquettes of neat cement even hardened under cold water expand and crack badly.

	Per Cent.	
SiO_2	20.0	
Al_2O_3	6.3	
Fe_2O_3	1.9	
CaO	66.0	$\text{CaO} + \text{MgO}$
MgO	0.9	$\text{SiO}_2 + \text{Al}_2\text{O}_3 = 3.1$
SO_3	1.2	
H_2O	2.5	
Undetermined	51.2	
	100.0	

* For the explanation of these ratios see Le Chatelier's work, *Recherches Experimentales sur la Constitution des Mortier Hydrauliques*, p. 871; the weights are molecular and not in percentages.

† 2.5 in original.

‡ 0.9 in original.

§ 0.7 in original.

The last three cements are of bad quality.

All these cements were tested in the same way, being made into briquettes composed of 1 part of cement to 3 of normal sand, using 11 per cent. of water for mixing, and immersing them 24 hours after gauging. In the case of those tested cold, they were broken at 7 and 28 days after immersion, while the others were kept in water at 80° C. for periods of 2 and 7 days. The results were as follows:—

	Cold.		Hot.	
	Tensile Strength in Kilos. per Sq. Cm.		Tensile Strength in Kilos. per Sq. Cm.	
	7 Days.	28 Days.	2 Days.	7 Days.
(1.) Good fine-ground cement	15.0	23.2	17.2	24.3
(2.) Coarse-ground cement..	6.7	13.7	7.6	11.0
(3.) Quick-setting cement...	6.2	16.5	7.3	16.2
(4.) Partly inert cement	2.9	3.9	Disintegrated.	
(5.) Underburnt cement	6.1	12.2		
(6.) Over-limed cement	7.6	20.2		

These figures need little comment. It must be noted, however, that there are two causes at work leading to the destruction of cements of bad quality: (i.) incomplete setting at the moment of immersion; (ii.) expansion due to the presence of free lime. The first of these is chiefly the reason of the failure of (4). On allowing it to set for 48 hours before immersion, no disintegration took place. Its tensile strength was then:—

	Hot.		Cold.
2 days	3.2	7 days	2.9
7 days	4.3	28 days	3.9

The similarity of the results obtained at 2 and 7 days hot to those at 7 and 28 days cold is worthy of notice. Overlimed cements disintegrate even if allowed several days to set before immersion in hot water. They can be rendered safe by exposure to moist air, so as to slake the lime previous to gauging, but of course lose enormously in strength when tested cold.

The following deductions may be drawn from these experiments:—

(1.) Tests made cold do not indicate the quality of the cement, inasmuch as cement containing excess of lime, and, in consequence, deplorably bad, may give excellent results.

(2.) Portland cement of good quality mixed with normal sand in the proportion of 1:3 resists water at 80° C. Its strength at 2 and 7 days after setting is about equal to that which it would have at 7 and 28 days in the cold.

(3.) Poor cement containing much inert matter does not resist the action of water at 80° C. unless the setting be allowed to proceed for some days before immersion. With this precaution, the relation between the tests hot and cold is the same as with good cement.

(4.) Cements containing free lime, whether because of the use of too large a proportion of chalk, imperfect mixture, or under-burning, do not withstand the action of water at 80° C. if immersed 24 hours after setting. When the percentage of free lime is tolerably small, whether so originally or after the bulk has been slaked by aëration, the cement will resist the action of hot water if immersed some longer time after setting. But in this case the tensile strength at 2 and 7 days hot is considerably lower than that at 7 and 28 days cold. Comparison of the strength hot and cold will suffice for the detection of even small quantities of free lime.

Further experiments were instituted on several kinds of hydraulic limes and cements. The results may be given briefly *seriatim*:—

(1.) Fifteen Portland cements, both "natural" (*i.e.* made from "cement stone") and artificial (from chalk and clay) were tested hot and cold. The figures obtained showed that the tensile strength at 7 days at 80° C. was approximately equal to that at 28 days cold, as in the former series of experiments. Where divergencies occur, they are always indicative of the greater utility of the hot tests, which favour the complete setting of the puzzuolanic material in certain highly siliceous good-quality cements, which sets with great slowness in the cold, and give low results with cements containing free lime, which cements may appear of high tensile strength when judged by a short-time cold test.

(2.) The results of six samples of slag cement which had been tested by *Prost* instead of *Deval*, are given in tabular form. In this case, the tests were made in compression, and the temperature used was 90° C. Moreover, the moulds were simply filled with the trowel, instead of the material (cement 1, sand 3) being beaten in. (For an account of the nature and composition of modern slag cements, see this Journal, 1890, 863.) It may be noted that in general slags rich in lime produce the best slag cement, provided that they can be preserved in the vitreous state by sudden cooling—a matter of some difficulty, as they tend to pass into the crystalline condition more easily than those containing less lime.

The general conclusions from these experiments are similar to those given above for Portland cements. The substitution of hot for cold tests would be particularly advantageous in the case of slag cements made with hydraulic as opposed to "fat" lime, as by this means samples made with hydraulic lime imperfectly slaked would be detected.

(3.) Eleven quick-setting cements made by burning argillaceous limestones at a temperature just high enough to drive off their carbon dioxide, and in consequence containing much free lime and but little of the more powerfully cementitious compounds formed at higher temperatures were tested hot and cold. But little agreement between the two series of results could be found, the figures for the hot tests at 7 days being in general higher than those of the cold at 28 days. It is difficult to say which method of testing ranges the samples most nearly in their true order of merit. Sufficient attention has not yet been paid to this class of cements, which has a somewhat limited use. The presence of free lime remaining unslaked, derived from the somewhat harder burnt portions that are liable to be present, would at least be detected by the hot test.

(4.) Experiments on 11 samples of hydraulic limes were also carried out. In order to understand their significance, Le Chatelier's views concerning the nature, composition, and properties of hydraulic lime must be recalled. Hydraulic lime is obtained by burning limestone rich in silica and poor in alumina. It should, after burning, contain sufficient free lime to cause its spontaneous disintegration by slaking. In consequence of the high percentage of lime no vitrification is to be feared, and a continuous system of burning can be used, economising fuel and lowering the price of the product below that of any similar hydraulic material. The active ingredient in hydraulic lime is the same tri-calcium silicate characteristic of Portland cement, *viz.*, $3\text{CaO}, \text{SiO}_2$. Less basic silicates of lime may be present which act as puzzuolanic materials with the free lime present, and bring about gradual hardening. Such aluminates as are formed become hydrated during the slaking process, and may be regarded as inert. Unless, however, the silica be in a fine state of division (in particles about $\frac{1}{1000}$ mm. in diameter) combination with the lime is difficult to effect in the absence of some alumina, which acts as a flux even as it does in the case of Portland cement. In order to obtain a product containing enough free lime, limestones must be used in which $\frac{\text{CaO}}{\text{SiO}_2 + \text{Al}_2\text{O}_3} > 3$. In practice about 4 equivalents

of lime would be required. But as complete combination cannot be expected, more siliceous limestones are generally used so as to get highly hydraulic products with a moderate consumption of fuel. Thus the Thell limestones, which may be regarded as a type of what an hydraulic limestone should be, contain 3 equivalents of lime to 1 of silica. The intimate relation between the proportions necessary for

good hydraulic lime and those requisite for good Portland cement is shown by the fact that this limestone yields excellent cement when burnt hard enough.

The proper slaking of the hydraulic lime after burning is at least as important a factor. In works where fuel economy is pushed to an extreme, under-burnt products are turned out, and if these were thoroughly slaked they would be of low tensile strength. In consequence there is a natural tendency to slake them imperfectly, the free lime which they contain causing them to give good results at first, although they become disintegrated eventually. Such materials would escape unnoticed by the cold test, but would be at once detected if tested hot.

Deval's experiments have been made with hydraulic limes of mediocre quality used in the Paris municipal works, and have been conducted on limes essentially different from those hitherto described. In order to test them under conditions similar to those obtaining in practice, the briquettes were gauged with a large percentage of water, so retarding the setting that as much as 6—30 days were allowed to elapse before immersion. The results are, in consequence, not directly comparable with those quoted above. It is at present impossible to draw any exact conclusions from the figures about to be given, but they are worth reproducing if only because of the absence of any previous experiments in this direction.

	Hot Water Tests.		Cold Water Tests.	
	Length of Time between Gauging and Immersion.	Tensile Strength at Seven Days after Immersion.	Tensile Strength.	
			25 Days.	Six Months.
	Days.	Kilos. per Sq. Cm.	Kilos. per Sq. Cm.	Kilos. per Sq. Cm.
A	10	8.4	2.15	7.60
B	6	8.4	2.15	7.60
C	6	7.8	1.45	5.50
D	26	7.1	1.70	7.05
E	26	6.0	2.20	5.00
F	20	5.4	1.95	7.05
G	18	5.2	2.15	7.90

The briquettes contained two parts of hydraulic lime to five of normal sand, the quantity of water used being about 70 per cent. of the weight of the lime.

Chatelier has supplemented these results by others made on similar materials, only more carefully manufactured. In this case a mixture of one of lime to two of normal sand was used, and the tests made in compression. The briquettes were immersed after 48 hours' setting. A second set of experiments was at the same time made with the same hydraulic limes slaked by being moistened with 10 per cent. of water, and dried for 48 hours at 100° C. and for other 48 hours at 150° C. The following figures were obtained:—

Sample,	Strength in Compression at Seven Days.		
	Kilos. per Sq. Cm.		
	Hot Tests,	Cold Tests,	
X {	In original state	107	28
	{ After re-slaking.....	82	14
D {	In original state	43	14
	{ After re-slaking.....	28	12
F {	In original state	43	12
	{ After re-slaking.....	57	12
G {	In original state	46	14
	{ After re-slaking.....	68	14

Samples X and D, seeing that they lose strength by re-slaking, may be considered fully slaked originally. Samples F and G are improved by re-slaking; hence it appears that they were originally badly slaked. Save for the conclusion that the hot tests tend to prevent hydraulic products being ranked as good if they contain free lime, few definite deductions may be drawn.

The extreme value of the method in this respect is yet again demonstrated by a comparison of the results given by some experiments made in 1884 on hydraulic limes from Teil, Saint Astier, and Pavier.

The composition of the raw material used for the first two is nearly identical, but the Teil hydraulic lime is well burnt and thoroughly slaked for 8—15 days, while that of Saint Astier is lightly burnt and the slaking occupies only 48 hours.

Kind of Lime.	Cold Tests.				Hot Tests.	
	7 Days.	28 Days.	42 Days.	Expansion.	7 Days.	Expansion.
Teil	12.5	19.5	39.0	Nil	69.0	Nil
Pavier	3.6	8.5	17.0	Nil	48.0	Nil
Saint Astier (1)	19.5	33.0	51.0	Slight	30.0	Per Cent. 15
Saint Astier (2)	16.5	21.0	27.0	Slight	15.0	30
Saint Astier (3)	8.0	13.0	33.0	Slight	7.5	30

The results are in kilos. per cm.

From this it is seen that the hydraulic limes from Saint Astier which contain free lime give higher results for short time cold tests than those from Teil, which are really far better than they. It is only after the elapse of three months that their respective merits can be rightly determined by cold tests, whereas they are correctly classed by the hot test in seven days.

Conclusions.—The conclusions drawn from this lengthy and most important paper are as follows:—Good hydraulic limes and cements are ranked in the same order, whether tested hot or cold. Products containing free lime which may pass the scrutiny of the cold test are condemned by the hot. Products containing puzzolanic matters, which are practically inert in the cold, rank higher when tested hot, inasmuch as these constituents react and add to their strength. The value of the hot test will be greatest for "natural" Portland cements and similar materials, the composition of which is not so thoroughly under the control of the maker as is that of ordinary Portland cement. It is not to be expected that manufacturers will view with favour the adoption of the hot test in engineers' specifications, as it differentiates good from mediocre cements rather too sharply. Cement users as opposed to makers will probably be prejudiced against it both on account of its novelty and because of the distrust engendered by the erroneous dictum of Michaelis, who first used the hot test, that there was a definite relation between results got by it and those obtained in the cold. This idea is completely exploded, and the fact of no such relation existing is the whole secret of its usefulness, for it permits of the elimination of certain thoroughly bad cements which escape detection by the cold test.

It would be injudicious to endeavour to substitute hot for cold testing all at once; the best plan to adopt is to institute the practice of making hot tests side by side with those ordinarily used, in order to ascertain, not whether any regular relation exists between them, but simply to gain the opportunity of studying the conditions of manufacture and ultimate behaviour in practice of such cements as show noteworthy divergences when tried by the two methods.

It must not be forgotten that the hot test can only replace the corresponding tests in the cold. The usual determinations of speed of setting and hardening must be retained.

To recapitulate the method of testing proposed, it may be said that the cement must be mixed with normal sand in the proportion of 1 to 3, the briquettes immersed at the end of

48 or 72 hours according to the speed of setting, and broken after seven days' exposure at 80° C. The results should be compared with those obtained at 28 days in the cold.—B. B.

A New or Improved Artificial Asphalt. C. Smith, London. From G. P. V. Nielsen, Frederiksberg, Denmark. Eng. Pat. 20,303, December 17, 1889. 4d.

This material is a mixture of resin, 13 parts, chalk, 26 parts, ordinary gravel, 53 parts, and tar, 8 parts; "a little natural asphalt" being added, "according to circumstances."

—E. G. C.

Improvements in Furnaces or Kilns for Burning Bricks, Tiles, and the like. G. Möller, Hohenlimburg, Germany. Eng. Pat. 3985, March 13, 1890. 8d.

In this invention the kilns are built so as to avoid having a large number of channels for carrying the gases or any inaccessible valves.

The air is led through a series of chambers, so that after being used for cooling bricks, the heated gas passes on, and subsequently passes out with the products of combustion and over unkilned bricks or tiles to preliminarily dry them. The orifices of the channels through which the air and gases pass are covered by means of lids with sand joints which can be attended to at any time if required.

There is also an improved arrangement for regulating the draught.—D. A. S.

Improvements in Kilns for Burning Bricks, Tiles, and other Clay Goods. E. P. Lee, Cardiff. Eng. Pat. 4504, March 22, 1890. 8d.

This is an improvement on kilns for burning bricks, &c., flues being built with dampers so that the communication between the kilns can be controlled in such a way that the surplus heated air and fumes, instead of being discharged into the atmosphere, are directed from any kiln in use into a fresh one, for the purpose of "steaming" or drying off, and heating the goods before being finally burnt.—D. A. S.

Improved Article of Manufacture for use as a Substitute for Wall Papers, Flooring, and other Ornamental Coverings. G. Baker, Birmingham. From H. Silver and S. S. Ritchie, Lindsay, Canada. Eng. Pat. 17,782, November 5, 1890. 8d.

"THE object of the invention is to produce a useful article of manufacture to be used as a substitute for wall paper, flooring, and other ornamental coverings, and it consists essentially of two or more strips of thin wood veneer cemented upon a backing of paper, cloth, or other flexible fabric."—E. J. B.

Improvements in and relating to Furnaces for Burning Bricks and the Like. L. Trevisan, Villaverla, Italy. Eng. Pat. 20,251, December 11, 1890. 6d.

THE burning of bricks is hereby continuously affected by means of combustion of gas generated by the distillation of coal in retorts placed in the interior of the furnace, coke being obtained as a by-product. The material to be burned is placed in the furnace, and some vertical retorts are built in proportion to the size of the compartment with bricks to be burnt preferably firebricks, a free space being left between the walls of neighbouring retorts to enable the flames to surround them. As soon as the temperature has been raised to a suitable point, coal is introduced gradually to the interior of the retorts. Thus the coal is only introduced when the retort is sufficiently hot for distillation.

—D. A. S.

X.—METALLURGY.

PATENTS.

Manufacture of Nickel and of Cobalt, and of Alloys of either of these Metals with Iron. A. M. Clark, London. From C. Combier, la Société Anon. "Fonderie de Nickel et Metaux blancs," Paris, France. Eng. Pat. 2243, May 2, 1883. (Second Edition.) 6d.

MALLEABLE and ductile nickel, cobalt, ferro-nickel, and ferro-cobalt are obtained by melting metallie nickel or cobalt with cyanide or ferro-cyanide of potash and oxide of manganese, soft iron being also added in the case of the alloys.

The mixture, when fused, forms a mass which is thoroughly stirred by the constant ebullition due to the disengagement of gases; when this ceases the temperature is raised and the metal poured into moulds.

"Given a peroxide of manganese containing a mean of 74 per cent. of metallic manganese, the best proportions are 12 parts of cyanide or ferro-cyanide of potassium to 100 parts of matters to be melted."

In the manufacture of ferro-nickel and ferro-cobalt, soft iron of the best quality should be used for alloying; the addition of a very small quantity of aluminium to the crucible ensures the homogeneity of the metal and facilitates the subsequent working.—S. B. A. A.

Improvements in the Manufacture of Metallic Alloys or Compounds. G. E. Vaughan, Middlesex. From L. Weiller, Angoulême, France. Eng. Pat. 18,211, December 13, 1888. (Second Edition.) 6d.

This improvement consists in the addition of a small quantity of zinc or spelter to copper or bronze containing silicon or sodium, or both silicon and sodium, for the purpose of improving the tenacity and ductility of the above alloys. If the resulting metal is to be of the nature of brass, the quantity of spelter added may amount to 40 per cent., but if bronze is required it must not exceed 5 per cent.

—H. K. T.

Improvements in Obtaining Alloys of Aluminium with Other Metals. J. Clark, Birmingham. Eng. Pat. 12,648, August 10, 1889. (Second Edition.) 6d.

WASTE materials containing aluminium silicate, also bauxite or eryolite, are mixed with quicklime, fluorspar, carbon, and sometimes common salt. The mixture is then ground up with water, dried and heated in a furnace in contact with fuel, until fusion takes place. The fused material is ground to powder and mixed with metal in small pieces, charged into crucibles and heated, when an alloy of the metal with aluminium is produced. The fused silicate may also be mixed with iron or steel in small pieces and charged into a blast or cupola furnace for the production of ferro-aluminium, or it may be used as a lining for a Bessemer converter or for the bed of a reverberatory furnace.

—H. K. T.

Improvements in and Connected with Steel-making and other Water-Gas Furnaces. W. Deighton, Leeds. Eng. Pat. 13,301, August 23, 1889. 8d.

THIS invention is designed to simplify the construction and arrangement of steel-making and other furnaces using "water-gas" as fuel, and for the elimination of non-metallie substances from the molten metallie bath in the form of vapour or gases.

The body of the furnace may be stationary, rotating, or otherwise, and a special feature is that it dispenses with all the usual arrangements for reversing the current or flow of the air and gas. The flow of air and gas is always in one direction through the furnace, and an extra jet of air or gas may be introduced at any desirable point. The waste gases are led through a second furnace in order to melt the metal so that it will flow freely into the first furnace to be finished.—D. A. S.

Improvements in Furnaces such as Cupola and Blast Furnaces. F. E. Ross, Croydon, Eng. Pat. 16,338, October 16, 1889. 8d.

THE hot gases and products of combustion that escape from the upper part of cupolas and blast furnaces are utilised by being drawn down and caused to re-enter the furnace at a lower part and to be completely burnt, thus effecting economy in the working. The jets of air usually blown in at the bottom may be used to induce the hot gases to flow and re-enter the lower portion of the furnace. A pump may, however, be used for the same purpose.

For melting metal in cupolas as ordinarily constructed and worked, it is necessary to use coke as fuel, but by re-constructing and working cupolas in the special way described it is claimed that coal can be used, as the coal will be converted into coke before it reaches the melting and combustion chamber. The combustible vapours driven off during the coking operation are drawn off with the hot gases withdrawn from the combustion chamber, and introduced with these gases into the combustion chamber by the inducing action of the air tuyere and are thus utilised.

There are two sheets of drawings completely illustrating this specification.—D. A. S.

Improvements in Treating Ores to Obtain Precious Metals, and in Apparatus therefor. T. Young, Glasgow, Eng. Pat. 20,181, December 16, 1889. 8d.

THIS invention consists of a new form of precipitating vessel for the lixiviation products of chlorinised ores, which is also adapted for use in other operations involving precipitation and filtration.

The vessel consists of a central cylindrical part bolted by flanges to a curved top and curved bottom, it is air-tight and completely lined with rubber. The top piece is connected with the space beneath the false bottom of the tank in which the chlorinised ores are lixiviated, and is fitted with pipes for the introduction of steam and liquid reagents. A vulcanite or protected metal discharge pipe communicating with a filter press passes through the top piece and dips down to the bottom of the vessel, a little above which there is a perforated vulcanite diaphragm on which crystals of ferrous sulphate or other reagents are placed. Before treating a charge, the air in the vessel is expelled by injecting steam, the latter on condensing dissolves the reagents on the diaphragm and causes a partial vacuum in virtue of which the solution in the tank is drawn over on opening a valve in the connecting pipe. When the precipitation is complete steam is again admitted, and the mixture forced through the discharge pipe into the filter press.—S. B. A. A.

Improvements in the Manufacture of Steel and Iron. J. Mackintire, Sheffield, Eng. Pat. 213, January 6, 1890. 6d.

THESE improvements are in the compounding of certain mixtures, the use of which in any modern steel-making process is alleged to ensure the production, from various grades of iron, of high-class metal of all kinds, and to render possible the manufacture of steel combining very high tensile strength, well defined elongation, and perfect soundness. The mixtures may also be used with good results in the puddling furnace. One composition consists of (1), 7 oz. of a mixture of 98½ per cent. calcium carbonate with 1½ per cent. of calcium phosphate; (2), about 5 oz. of black oxide of manganese; (3), ½ oz. of tannin; (4), 6 oz. of vegetable soot well mixed with 2 oz. of bone black; (5), 2 oz. of tar well mixed with from 2 to 3 oz. of water. To the last ingredient first (4) is added, then an intimate mixture of (1), (2), and (3), and the whole is triturated into a compact cake. This is introduced into the crucible either with the charge of cold metal or into the molten mass. The above ingredients may with some advantage be used in the form of an iron alloy, especially in the Bessemer converter. 1½ lb. of the mixture of calcium carbonate and phosphate, 1½ lb. of manganese dioxide, 1½ oz. of tannin, ½ lb. of soot, ½ lb. of animal black, and 1 oz. of tar made

into a paste with water and formed into a cake, is added to 40 lb. of hematite pig melted to a pasty condition, covered with 26 lb. of cold pig, and the whole run down and cast into moulds. When required for use the alloy is re-melted in a cupola, and run into the converter at the termination of the blow, no spiegel or lime being added, a further blow of about one-half minute is given and the metal tilted into the ladle and cast. The proportion of the alloy added may be varied up to 16 per cent. of the iron, but when a steel containing more carbon is required the alloy is melted with a sufficient quantity of pig iron for the Bessemer and open-hearth processes, and the carbon is directly added as wood charcoal in the crucible process. Improved iron castings may be made from equal parts of the alloy, scrap iron, and pig iron, also with a smaller proportion of the alloy according to requirements. In the puddling furnace the alloy or mixture should be added before the molten iron comes to nature.—S. B. A. A.

Improvements in the Extraction of Metals from Ore or other Material containing them, and Apparatus therefor. J. E. Chaster, Shawlands, Eng. Pat. 316, January 8, 1890. 8d.

THIS invention relates to a new form of amalgamating pan in which the mercury is kept from sickening by the passage of a current of electricity. It consists of an oblong trough containing mercury and closed at one end by a perforated iron plate or wire gauze for the discharge of water and tailings. Resting upon the mercury and nearly filling the trough there is a rectangular framework with a perforated base of which the upper or under surface is covered by a metal plate separated from the mercury by a diaphragm of some porous material such as canvas or raw hide. This plate forms the anode of the circuit, the mercury forming the cathode. One side of the framework is depressed below the surface of the mercury, and has attached to it a high vertical shoot or feed pipe opening below the framework and containing a head of water and ore sufficient to overcome the pressure of the mercury. The whole framework is oscillated by suitable machinery from side to side of the trough. In the treatment refractory ores the trough may be heated by means of a steam chamber placed below.

—S. B. A. A.

Improvements in the Manufacture of Copper. T. Twynam, Bedford Park, Eng. Pat. 560, January 11, 1890. 4d.

ACCORDING to this invention copper mattes, coarse metal, cupola metal, and other cupriferous products containing a large percentage of iron may be converted into blister or refined copper in a single operation. The matte or coarse metal, or a mixture of these substances with copper precipitate, is mixed with the necessary quantity of siliceous material, preferably siliceous copper ore or slags, and charged into a Siemens or reverberatory furnace provided with a lining of chrome iron ore made coherent by either of the methods previously described in Eng. Pat. 8358 or 8359 of 1886 (see this Journal, 1886, 494). When a reverberatory furnace is employed an air blast may be used to promote the oxidation of the iron. The slag formed is skimmed off at intervals, siliceous material being added if it be not readily fusible. When the iron is removed or nearly so the copper remains as white or purple metal, which after complete removal of the slag is treated at intervals with small quantities of lime, and the operation continued until the metal is converted into blister or refined copper. Chrome iron lined furnaces may be advantageously employed in melting copper precipitate as the lining is not attacked. Cupriferous materials containing much arsenic and not less than 50 per cent. of copper may be bessemerised in chrome iron lined converters with special advantage. In this case when the iron and the sulphur have been oxidised and removed in the slag, a suitable basic addition such as a mixture of lime and soda ash is made, and the blowing continued until the arsenic passes into the slag formed.—S. B. A. A.

Improved Construction or Arrangement of Apparatus for Coating Hoop Iron with Tin or Terne Metal. T. H. Johns, London. Eng. Pat. 1522, January 28, 1890. 6d.

This apparatus consists of a flat perforated tube immersed in a bath of molten tin or terne metal, through which the hoop iron is caused to travel. On issuing the edges of the hoop iron are caught by rolls set vertically, and the hoop iron is forced between adjustable scrapers. It afterwards meets a current of cold air for the purpose of causing the metallic coating to set.—H. K. T.

An Improved Process for Treating Iron and other Ores, and Apparatus therefor. M. R. Conley, Brooklyn, and J. H. Lancaster, New York, U.S.A. Eng. Pat. 1806, February 3, 1890. 11d.

This is a direct reduction process and consists in the deoxidisation and also desulphurisation and dephosphorisation of iron or other ore by heating it in a closed retort with hydrocarbon gases. A metal or fireclay retort partially surrounded with firebricks, provided with a swinging door at one end and supported within a brick setting, is heated externally by gaseous or solid fuel to 1,500° F. The granulated ore is charged from a hopper car through a deep shoot, the mouth of which is immediately secured; producer-gas is then injected and the mass kept in agitation by a series of stirrers carried on a central shaft revolving in bearings at either end of the retort. Intermittent rabbling may be substituted for the mechanical stirrers, but in this case precautions must be taken to minimise the access of air. The waste gas passes off through a narrow exit pipe, and may be utilised as fuel. The reduction is complete in 3 to 6 hours, and is indicated by the appearance of the ore or of the issuing gases. The door is then raised and the mass rapidly emptied through a shoot immediately beneath the door into a closed moveable car in which it is conveyed to the roof of an open-hearth furnace, and charged through a suitable aperture by opening a valve in the base of the car. The contrivances described have for their principal object to prevent access of air to the retort, and to the granular or spongy iron during transit to the melting furnace.

—S. B. A. A.

Improvements in the Method of Precipitating Gold or Silver in the Process of its Extraction. J. Buchanan, Glasgow. Eng. Pat. 2390, February 14, 1890. 4d.

The solutions of gold and silver obtained in the chlorination processes are allowed to percolate through iron or steel borings, or some other finely-divided metal or alloy capable of precipitating the above metals. When the solution contains copper it is first allowed to percolate through copper turnings, whereby the bulk of the gold and silver is thrown down. It is then treated with iron, when the copper with the rest of the gold and silver is precipitated. The precipitated metals are removed by riddling and washing the turnings and filtering out the suspended metal; or the precipitating metal may be kept in agitation whilst the precipitation is going on, the gold and silver being afterwards obtained from the liquor by filtration, or by allowing the precipitated metals to settle.—H. K. T.

A Process for Extraction of Tin from the Slag or Débris of Tin Smelting. T. Teague, Devoran. Eng. Pat. 5638, April 14, 1890. 4d.

Tin slags or débris in fragments are mixed usually with about 10 per cent., but if necessary with 10–25 per cent. of smaller fragments of flint or other spar, elvan blue or mixtures of these, preferably along with a little lime, and, in cases where there is little or no reducing material in the slag, coal-dust or other powdered carbonaceous matter is added. The whole is well mixed in a pot, run down, and teemed into a sand mould of sugar-loaf form. After cooling the cast is removed and the tin is found collected in a button at the bottom.—S. B. A. A.

Improvements in or relating to the Art or Process of Galvanising Metal Tubes and Bars, and in Means or Appliances for use therein or relating thereto. T. L. Thomas and J. B. Hillman, Tipton. Eng. Pat. 8572, June 3, 1890. 8d.

Is the usual method of galvanising, the articles to be coated, after immersion in the molten bath, are withdrawn slowly from the metal through a special flux, and are placed on line edges and rotated until the coating has set. The patentees, however, remove the article rapidly and draw it through asbestos dies, whereby a more even coating is effected, and less waste of metal is occasioned. The article is then immersed in a water-bath.—H. K. T.

Improvements in Smelting Furnaces. F. A. Herbertz, Cologne, Germany. Eng. Pat. 14,053, September 6, 1890. 6d.

In this furnace the draught is caused by means of suction produced by a steam jet, the air entering the furnace by means of circular adjustable apertures. The furnace consists of a fixed stack S, below which are suspended by

IMPROVED SMELTING FURNACE.

means of the hanging bolts B, B₁, two water-jacketed annular chambers K, K₁, an annular space O being left between them for the entrance of air, which also enters through the space O left between the lower annular chamber and the moveable hearth H. The draught is caused by a steam jet J, which draws the products of combustion through the flues R, R₁. In order to prevent the choking of the flues by mechanically suspended particles the upper of these, R₁, is removable and can be replaced by a similar flue so as to allow of its being cleaned without interrupting the process. Finely-divided ore is introduced through the shoot D into the body of the furnace, coke and coarser material being added through the shoot V.—H. K. T.

Improvements in Apparatus for Decomposing Metallic Salts and Desulphurising Ores. H. R. Lake, London. From O. B. Peck, Chicago, U.S.A. Eng. Pat. 16,545, October 17, 1890. 8d.

This apparatus consists of a receiving vessel in which the metallic salts or ores are treated in a molten condition and which may be rotated at a high speed upon a central vertical shaft. This vessel is provided with one or more cast-iron linings, slightly incomplete to allow for expansion, the open slits being provided with cover-pieces. The lining for the neck and mouth of the receiving vessel is made with vertical recesses into which are dovetailed blocks with channels in their faces, and around the upper part of the vessel is an annular tub into which the molten substances under treatment forced up the channels by centrifugal force finally subside. A device is also shown for cooling the vessel by the circulation of water. (Compare Eng. Pats. 17,069 of 1888 and 10,288 of 1889; this Journal, 1889, 400 and 868.)—S. B. A. A.

Improvements in the Manufacture of Steel and Ingot Iron. P. M. Justice, London. From J. Meyer, Durlach, Germany. Eng. Pat. 17,613, November 3, 1890. 1d.

This is a process for the direct introduction of carbon into iron which has been decarbonised and dephosphorised in acid or basic converters or in Siemens-Martin furnaces. A mixture is made of 95 parts of powdered charcoal or anthracite coal and 5 to 8 parts of quicklime, the whole being made into a paste with water and left for 12 to 30 hours. The mixture is then made into briquettes and dried.

In order to effect recarbonisation, one-third of the total weight of briquettes to be used is placed in the casting ladle, and the molten metal, previously freed from slag, is poured upon it, the remainder of the briquettes being added to the metal whilst it is being poured into the ladle. A portion of the carbon is oxidised furnishing a large amount of heat, so that there is no danger of the metal setting whilst being poured. The lime which the briquettes contain combines with the silica of the ash and rises to the surface as a fusible slag. It is advisable to break this crust during the recarbonisation so as to allow free escape for the gases produced by the combustion of the carbon.

The following are the quantities of briquettes required for the recarbonisation of a metric ton of pig iron:—

Pig Iron.	Per Cent. of Carbon.
2.5 to 2.8 kilos. of briquettes for steel with	0.10 to 0.15
3.0 to 3.2 " " "	0.15 to 0.20
3.0 to 3.5 " " "	0.25 to 0.30
5.0 to 5.5 " " "	0.30 to 0.35
6.5 to 7.0 " " "	0.40 to 0.45
7.0 to 7.5 " " "	0.45 to 0.50

—H. K. T.

Improvements in or Appertaining to the Manufacture and Tempering of Steel. W. P. Thompson, Liverpool. From M. F. Coomes and A. W. Hyde, Louisville, U.S.A. Eng. Pat. 18,174, November 11, 1890. 1d.

According to this invention malleable cast iron or soft steel is carburised by placing the white-hot metal in a bath composed of water, sugar, common salt, and ammonium chloride, and allowing it to remain there whilst cooling. To prepare the bath, sugar is added to a saturated aqueous solution of common salt until no more is dissolved; the compound solution is then saturated with ammonium chloride. This solution may also be used as a tempering bath in the ordinary way.—S. B. A. A.

Improvements in the Manufacture of Coated Aluminium Plates or Surfaces and in the Application of the Same for Coating or Soldering to Other Metals. W. P. Thompson, Liverpool. From C. H. Land, Detroit, U.S.A. Eng. Pat. 18,915, November 21, 1890. 6a.

The inventor finds that pure tin will unite with aluminium at a temperature above the melting point of tin provided the heated metal is burnished over the surface of the

aluminium. Aluminium plates are in practice coated with tin by immersing them in a bath of the molten metal and burnishing them whilst immersed; such plates may then be soldered with pure tin or common solder, or may be united with tin-plated metals by heating both plates and pressing them together. The method is useful for attaching aluminium facings to metallic surfaces, and in the manufacture of aluminium cylinders for compressed air. The latter may consist of a tin-coated aluminium plate folded over into a cylinder of as many thicknesses as desired and sweated together, a tin-coated aluminium wire may then be likewise wound around the cylinder and sweated on.—S. B. A. A.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

The Elmore Copper-Depositing Process. Engineering, 1891, 51, 141—142; and Engineer, 1891, 71, 178—179.

The copper is brought into the works in its rough state as Chili bars. These contain about 97 per cent. of pure copper, and in the remaining 3 per cent. are present about $\frac{1}{2}$ oz. of gold and 3 oz. of silver per ton. The Chili bars are first melted in a furnace, and the molten metal is poured into a crucible which holds about a ton. The crucible is carried on a small truck, which runs over a light track, and the metal is poured into a large tank of water in order to granulate it, so that it may be in a suitable condition for use in the tanks.

The depositing tanks are made of wood, coated inside with a bituminous composition. At the bottom of each tank is fixed a perforated copper plate, which is covered with the granulated copper. The tanks contain a solution of sulphate of copper in water, with a small quantity of sulphuric acid. When it is desired to make a tube, an iron mandrel, the size of the bore of the tube, is placed horizontally in the tank, being held at each end in bearings. Before being placed in the bath the mandrel receives a thin coat or film of copper, by means of the ordinary cyanide process. The mandrel is caused to revolve in the bath by means of chain gearing run by suitable mechanism. The mandrel thus forms a cathode, whilst the anode consists of the granulated copper which is spread on the perforated tray at the bottom of the bath. The average density of the electrolyte is 16.5 B.

Although it would appear that there ought not to be much difficulty in manufacturing a cast iron tube 10 ft. or 12 ft. long, and of even thickness throughout its length, and without sponginess, yet it appears to be extremely difficult. When the mandrel is thicker at one part than the other, it causes uneven rotation, and it is very liable to break the driving chain, and if it be at all spongy the holes in the surface become filled with the copper deposit, and it is impossible to release the tube from the mandrel. The method now in use is to fill up any small flaws in the surface with lead, and then to deposit a thin coating of copper upon the mandrel by the ordinary cyanide process. The copper which is afterwards deposited on it does not adhere to the thin copper layer with which the mandrel is coated, it being found that an exposure to the air for even a short period produces a coating of oxide which effectually prevents adherence, so that if a mandrel were not in stock of the size required, a tube could be deposited over another tube.

The burnishing, which is the great distinctive feature of the Elmore process, is accomplished by means of an agate, held in a suitable holder and pressed against the work—which is of course beneath the surface of the bath—by means of elastic bands, which allow of an adjustment of pressure sufficiently accurate for the purpose. This agate burnisher is caused to traverse the whole length of the tank at such a speed that the advance made whilst the mandrel completes one revolution is equal to the longitudinal dimension of the agate. The action is similar to

that of screw-cutting in a lathe, and it will be evident that every part of the tube being formed is gone over by the agate once in each traverse.

The loss of pressure in each tank is generally about 0.9 volt. The current density is about 16 amperes per square foot of cathode surface as an average for ordinary work, but it may fall to 12, or rise as high as 20 amperes. It might be objected that, working at such high current density, hydrogen would be evolved and occluded in the copper deposited, but such is not found to be the case. In this process all the conditions are very favourable to working with high current density. In the first place the density of the liquor throughout the tank is kept uniform by means of the circulation due to the rotation of the horizontal mandrel, the conditions being very different from those which are present when the deposition takes place with a vertically-placed and stationary cathode. In the next place the deposited surface is kept quite smooth by means of the burnisher, and there are thus no points to induce an extra discharge of current in one place. Thirdly, by the rotation of the mandrel fresh particles of liquor, always strong in sulphate of copper, are constantly being brought in contact with any given area of surface. Further, the electro-motive force is below one volt per tank, and the electrolyte being uniform, the evolution of hydrogen is not to be anticipated.

The deposit is at the rate of about $\frac{1}{8}$ in. thickness of metal per week; therefore a 12 ft. by 2 ft. tank would turn out one 18 in. tube in a week of 168 hours, for it is practically a necessity of the system that it should be continuous so long as work is being carried on. Such a tank would therefore produce 275 lb. to 280 lb. of copper tube in one week. A tank of approximately the same size would produce two 9-in. tubes or three 6-in. tubes of the same total weight.

After the deposition has been completed, the mandrel is removed from the bath, for the purpose of withdrawing the tube. The copper is, of course, a tight fit on the mandrel, and in order to loosen it, the whole is placed in a machine by which three rollers are pressed on the tube, and traversed along the length of the pipe. The pipe and mandrel are caused to revolve at the same time, the motions being similar to those of screw-cutting in a lathe. The squeezing of the copper between the rollers and the mandrel causes a slight extension of surface, and therefore an increase of diameter. The pressure is regulated so that the tube is only expanded enough to make it a sufficiently easy fit to be stripped off the mandrel. Another machine, with circular cutters, removes the rough unburnished ends. In one machine the expansion and parting of ends is carried on at one time.

The sludge which gradually settles at the bottom of the tanks is run off with the spent electrolyte into large settling tanks, and when a sufficient quantity is obtained it is then smelted.

The copper is produced of different qualities, according to the use to which it is to be put, and the quality is varied by a difference in the solution and by the difference in the pressure of the burnisher upon the tube.

The following are the results of some mechanical tests made by Unwin on strips cut from tubes. The results are the same, whether the sample be cut longitudinally or circumferentially from the tube:—

Strip	1.226 × 0.049 in. section.
Area,	0.006074 square inch.
Broke with	2.36 tons = 39.27 tons per square inch.
Ultimate elongation,	5.1 per cent. in 10 in.
Strip	1.221 × 0.050 in. section.
Area,	0.006105 square inch.
Broke with	2.52 tons = 41.28 tons per square inch.
Elongation,	7.0 per cent. in 10 in.

Kennedy found the tensile strength of some specimens to vary between 25.92 and 26.83 tons, with an elongation of 17 per cent. in 4 in.

The copper produced by this process seems to be particularly suitable for wire drawing. Wire has been drawn down to a diameter of $\frac{1}{1000}$ in. in diameter without annealing. Some tests with wire produced by this process showed that the practical limit of hardness had been reached. Wire 18 B.W.G. (0.113 in. diameter) was drawn through 13 holes until the diameter reached 0.057 in., when the

breaking strain was 29 tons per sq. in., with an elongation of $\frac{3}{4}$ per cent. In spite of the hardness it was found to have an electrical conductivity about $2\frac{1}{2}$ per cent. higher than that of soft annealed wire of the best quality to be procured commercially. Wire subjected to torsion gave the following, the length of the wire being 3 in. between jaws of machine:—0.113 in. diam. (205 lb. per mile); breaking strain 27.4 tons with elongation of 2 per cent.; number of twists 31 in the 3 in. Wire 0.050 in. diam. (40.8 lb. per mile); breaking strain 28.4 tons; elongation $\frac{3}{8}$ to 1 per cent.; number of twists 47.—O. H.

PATENT.

Improvements in the Manufacture of Manilla Paper. J. B. Atherton, Hulton. From L. B. Beck, New York, U.S.A. Eng. Pat. 11,021, July 15, 1890. 8d.

See under XIX., page 268.

XII.—FATS, OILS, AND SOAP MANUFACTURE.

PATENTS.

Improvements in or Connected with the Manufacture of Oil Cake. F. C. Calthorp, Liverpool. Eng. Pat. 1471, January 28, 1890. 8d.

See under XVIII. A., page 266.

Improvements in or Appertaining to the Manufacture or Shaping of Soap. R. C. Scott, Lancaster. Eng. Pat. 3601, March 6, 1890. 8d.

Bars of soap are shaped with two or more sides deeply corrugated or with semi-spherical indentations, so that they may be firmly grasped, and also that they may drain and dry quickly when taken out of water, thereby lessening waste.—K. E. M.

Improvements in Decolourising Vegetable Oils in the Manufacture of Pale Drying Oils and Varnishes, and Apparatus therefor. W. N. Hartley, Dublin, and W. E. B. Benkinsop, London. Eng. Pat. 11,629, July 24, 1890. 8d.

A MANGANESE soap or other suitable organic compound of manganese is dissolved either direct in the oil under treatment, or in any suitable solvent (such as turpentine), and this solution added to the oil. Preferably the insoluble impurities are now removed. The clear oil is treated with a current of air or oxygen at a suitable temperature, generally at 190 F. In the manufacture of pale drying oils or varnishes, such as "boiled oil," manganese linoleate is preferably employed, 1 part of the latter to 800 parts of the oil. Oils containing much mucilage and water are mixed with about 1 per cent. of dilute sulphuric acid of 1.29 sp. gr. at 60 F. Should the acid used be too strong a coloring matter is produced which is not easily removed from the oil. Mucilage may also be removed by adding 1 part of a strong solution of manganese sulphate to 100 parts of the oil, and agitating. Drawings of an arrangement of apparatus adapted for carrying out the process accompanies the specification.—K. E. M.

Improvements in Cleansing and Polishing Compositions. E. Bietski, Cardiff. Eng. Pat. 16,979, October 24, 1890. 6d.

SPECIFIED proportions of dry soap (Hudson's dry soap) and yellow soap (Primrose soap) dissolved in water are boiled with whiting, whereby a paste is obtained for polishing and cleaning metals and glass.—K. E. M.

XIII.—PAINTS, PIGMENTS, VARNISHES, AND RESINS.

PATENTS.

A New or Improved White Pigment. H. Grimshaw, Manchester. Eng. Pat. 985, January 29, 1890. 44.

THE white pigment in question is a basic chloride of zinc, prepared either by dissolving metallic zinc in a solution of chloride of zinc, and precipitated by cooling, with or without the addition of an alkali, or by mixing zinc oxide with a solution of zinc chloride, and grinding the mass, when set, to a fine powder.—E. G. C.

Improvements in Imitation Whalebone. H. M. Knight, London. Eng. Pat. 1765, February 1, 1890. 6d.

THE inventor coats metal strips or cores with vulcanised india-rubber. The resulting imitation whalebone is stated to be not liable to crack or break.—E. G. C.

An Improved Glue Compound. T. O. Butler, Chicago, U.S.A. Eng. Pat. 17,853, November 6, 1890. 6d.

A MIXTURE of common glue, Paris white and sulphur. —E. G. C.

Improvements in Vulcanisers. J. H. Cartell, Penzance, and F. Knorferl, London. Eng. Pat. 20,005, December 8, 1890. 6d.

See under I., page 241.

XV.—MANURES, Etc.

PATENT.

An Improved Method of Nitrogenising Substances in the Manufacture of Manures and for other Purposes. H. Fewson, Buckingham. Eng. Pat. 20,076, December 13, 1890. 8d.

A "VEGETABLE PREPARATION" is made by grinding any refuse matter containing suitable vegetable acids (malic, malic, citric, tartaric, tannic, oxalic, benzoic, acetic, or gallic) and boiling it with water containing a suitable alkali, "one bushel of vegetable matter to ten gallons of water and one quarter of an ounce of sulphate of soda," being good proportions. This preparation is added to the sewage in the proportion of half a cubic inch per gallon of sewage, either in the sewer or at the outfall. Two to four grains of lime or other alkali are then added, and the sewage subjected to the action of high potential electric currents by being caused to pass through a box or sewer containing an iron electrode, so disposed that the liquid shall flow over it and a "platinum or other suitable electrode," which is maintained at a height of about one inch above the surface of the sewage. Filtration completes the process.

It is claimed that this treatment precipitates the solid matters and at the same time enriches them in nitrogen, the effluent being clear and colourless. The electricity is said to cause the absorption of nitrogen. A. G. B.

XVI.—SUGAR, STARCH, GUM, Etc.

The Juice of the Berries of the Mountain Ash, and the Formation of Sorbose. A. Freund. Monatsch. 11, 560—578.

ALL attempts to isolate sorbose from the fresh juice were unsuccessful, so that it must be concluded that this sugar is not present in the ripe berries. When the expressed juice, which has a specific gravity of 1.125, is kept for 13 months, sorbose is not formed, but if the juice is diluted with water until it has a specific gravity of 1.09, and then kept for six months, a considerable quantity of the sugar is produced. A specific gravity of 1.09 to 1.06 seems to be most favourable to the formation of sorbose.

The best way of preparing pure sorbose from the juice of the berries of the mountain ash is the following:—The expressed juice is diluted with water until it has a specific gravity of 1.09 to 1.06, and after 10 to 12 months a portion is evaporated to a thick syrup to ascertain whether a sufficient quantity of sorbose has been produced; under favourable conditions a crop of crystals, equal in volume to about half that of the syrup, is deposited in the course of a few days. The crystals are separated from the mother-liquors, placed in linen bags, and submitted to a pressure gradually increasing up to 300 atmospheres; the cake is then rubbed to a thick paste with a little water, pressed again, dissolved in water, a little albumen added, the solution boiled and filtered; on evaporating the filtrate, decolourised with animal charcoal if necessary, to a thin syrup, the sorbose is deposited in large crystals, and can then be further purified by recrystallisation from boiling 80 per cent. alcohol.—F. S. K.

Corrections to be made in the Abstract of Fischer's and Pilot's Paper on Sugars richer in Carbon from Rhumose. Ber. 23, 3827.

Apparatus for Drying Sugar or like Substances. R. Pzillas, Brieg, Germany. Eng. Pat. 10,893, July 12, 1890. 6d.

SEVERAL waggons, open only at their ends, and provided with shelves to carry the material, are locked firmly together, thus forming a closed channel and tube, running on rails. At one end is a fixed chamber and at the other a moveable one connected with a hot-air apparatus, both being very slightly larger than one of the waggons, and provided with doors for the entrance and removal of the waggons, and having also suitable air flaps. Above the fixed chamber is placed an exhaustor by which air is drawn from the heater through the entire length of the channel (or waggons). The waggons being made continuous with the two chambers, are propelled by rackwork, from the fixed to the heating chamber, where each is removed with the material dried, and being again loaded is transferred to the fixed chamber, and so on. The object of one chamber being made moveable is to allow of alteration in the number of waggons employed.—E. S.

Improvements in the Manufacture of German or Dried Yeast, part of which Improvements is applicable to the Production of Vinegar. J. Fordred, London. Eng. Pat. 5891, December 28, 1883. (Second Edition.) 6d.

A WATER containing a large amount of calcium sulphate is employed for mashing a grist in which rye-meal preponderates, as, for instance, 50 parts of rye, 20 parts of maize, 5 parts of oats, 25 parts of barley malt. A wort is produced of a "gravity ranging from 1.015 to 1.095 degrees"; if this be deficient in yeast-food a little spent wash is added to it. The wort is cooled to 70° F., and pitched with 8—10 lb. of fresh yeast to 100 gallons of wort. The yeast should be carefully selected, the cells should be plump and translucent with thin cell walls and few empty or shrivelled cells. The wort should be aerated by a rouser. As the yeast is formed it is removed in the ordinary way, strained through fine sieves and pressed in a filter-press. In some cases the yeast may be washed in the press by pumping through cold water containing a little phosphate. The fermentation is stopped when the attenuation has reached about 8°, and the fermented liquor converted into vinegar by the German quick method, or by stoving as practised in England.—A. L. S.

Manufacture of Amyloins applicable for the Treatment of Beer. H. T. Brown and G. H. Morris, Burton-on-Trent, and E. R. Moritz, London. Eng. Pat. 1809, February 3, 1889. 4d.

THIS material is manufactured by boiling together 100 parts of starch, 300 parts of water, and 3 parts of sulphuric acid, in a strong vessel provided with an agitator. If the boiling be carried on under pressure, not more than one-fifth of the above quantity of acid must be used. Samples are taken from time to time, and when the product has an optical activity of $[\alpha]_D^{20} = 193^\circ$, and a cupric oxide reducing power of 21, and the solution gives a full red colour with iodine solution, the reaction is stopped. The product obtained is suitable for addition to beer, on which it is said to have considerable effect in improving its qualities in respect of body, flavour and briskness.—A. L. S.

Improvements in Rousing Beer and Mixing or Blending Wort or Gyle, and in Apparatus employed therein. J. F. Littleton, Kingston-on-Thames. Eng. Pat. 1996, February 6, 1890. 8d.

THE apparatus consists of a vessel which may be lowered into or raised out of the fermenting liquor. The vessel is furnished with a lifting valve at the bottom, so that as it is lowered it quickly fills with liquor and is perforated with fine holes, so that when raised above the surface of the liquor this flows through the perforations, washing in the head of yeast, and effectually rousing the whole. The inventor also proposes to use a pump for the same purpose, the liquor being drawn from the lowest part of the fermenting vessel, and delivered in a fine spray on to the surface.—A. L. S.

An Improved Apparatus for the Aëration of Beers, Wines, Mineral Waters, and other like Liquors. B. J. Sharp, London. Eng. Pat. 2471, February 15, 1890. 8d.

THIS consists of a chamber to contain the liquid to be aerated, with a perforated false bottom, through which carbonic acid gas is forced from a reservoir of compressed

gas. The apparatus may be used in connexion with an ordinary bottling machine. A drawing of the apparatus accompanies the specification.—A. L. S.

Improvements in Apparatus for Generating and Supplying Carbonic Acid Gas to Vessels containing Fermented Liquor. H. S. G. Stephenson, Lymington Manor. Eng. Pat. 2990, February 25, 1890. 8d.

A SIMPLE apparatus for the constant evolution of carbonic acid, similar to those in common use in chemical laboratories, is connected with a cask of beer, so as to keep up a small but constant pressure of carbonic acid within the cask as the beer is drawn off.—A. L. S.

A New or Improved Process for the Recovery and Utilisation of Yeast. J. Campbell, Glasgow. Eng. Pat. 7195, May 8, 1890. 6d.

THE worts of a specific gravity of about 38—48° are set to ferment at 73°—76° F. "When about 8—12° of gravity remain unattenuated" the yeast is collected by skimming, tapping or other means into a vessel provided with an attenuator by which the temperature of the yeast is reduced down to 55—45° F. The yeast is allowed to stand in the back until it settles, when the liquid between the top and bottom layers is drawn off and the yeast is collected as for re-use as "ordinary brewers' yeast."—A. L. S.

A Composition for Refining and Heading Malt Liquors. G. Roskilly, London. Eng. Pat. 14118, September 8, 1890. 4d.

TO make six gallons of the composition, 3 lb. of quillain are steeped in 12 gallons of water for 30 hours, 5 lb. of nettles added, and the whole boiled down to 6 gallons; when cooled to 60° F. add 1 lb. of golden hop and raise to 210° F., then strain and when cool add 3 lb. of Russian isinglass; after standing 12 hours it is fit for use in the proportion of one pint to one barrel of malt liquor.—A. L. S.

Improvements in the Treatment of Alcoholic Liquids. E. J. Mills and R. Barr, Glasgow. Eng. Pat. 18212, November 12, 1890. 4d.

THE spirit is placed in a vat and air blown through it, at first rapidly and afterwards more slowly. During the aëration a small quantity of sherry or other similar wine is added (about one pint to 80 gallons of spirit). If the spirit is very coarse a small quantity of potassium hydrogen sulphate or sulphuric acid is added at the same time. This treatment may continue for a few minutes or several days, but six hours is an average time.

The spirit is finally transferred to casks, when in about three months it will have acquired about three years' age.—A. L. S.

Apparatus for Detaching and Removing Acrospires and Shoots from Malt. S. Hirschler, Worms-on-the-Rhine, Germany. Eng. Pat. 19,198, November 25, 1890. 6d.

THIS consists of a hollow cylinder arranged horizontally, having radial bolts projecting into and fixed to the sides of the cylinder. Through the centre passes a rotating shaft provided with radial beaters. The bottom of the cylinder is perforated with holes of a convenient size to allow of the passage of the acrospire, &c., but not of the malt. The malt is fed into the cylinder at one end and passes out at the other, through an opening in the end cover, which can be adjusted to different heights by turning the cover on the axis of the cylinder.—A. L. S.

PATENTS.

An Improved Process for the Production of Dry Extract of Coffee. H. Barotte, Paris, France. Eng. Pat. 19,882, December 10, 1889. 81.

The roasted and finely ground coffee is introduced into a jacketed cylinder connected with a copper condensing sphere; the cylinder is rotated during the process, and is heated by passing superheated steam into the jacket. A vacuum is maintained in the sphere and cylinder until the temperature of the latter reaches 160°, after which the pressure is allowed to increase rapidly, and when there is only 10 cm. of vacuum the steam is shut off and the apparatus left for five or ten minutes until the temperature rises to 210° C.; at this point cold water is at once injected into the jacket.

The distillate is filtered and immediately added in suitable proportion to a pulverised extract of the residual coffee in the cylinder, prepared by throwing the residual coffee into hot distilled water and evaporating the infusion thus obtained *in vacuo*. The mixture is finally dried *in vacuo* either by heat or over absorbents, and the resulting powder is called "Express Café."—A. G. B.

Improvements in or Connected with the Manufacture of Oil-Cake. F. C. Calthorp, Liverpool. Eng. Pat. 1471, January 28, 1890. 8d.

The object of this invention is the improvement of hard-pressed oil-cake as a cattle food. The cake is either steamed or soaked in some vapour or liquid and subsequently dried; or it may be first broken up by a dry or wet method, and then again pressed into a cake with or without the addition of substances to moisten and render it adhesive.—A. G. B.

Improvements in the Treatment or Regeneration of Yeast to be used in the Process of Bread-making, and in the Preparation of Paste and Dough for Pastry-Cooks and Biscuit-Makers. E. Lecomte, Estates, France. Eng. Pat. 3856, March 11, 1890. 6d.

In order to render the yeast as supplied to bakers more active, the crude yeast is made into a thin cream with water at about 70–100° F., and a syrup made from malted barley or other malted cereal is added. This is allowed to stand for about one hour, and it is then mixed with paste or dough, as is usual in the ordinary process employed by bakers, &c.

The inventor claims that by this method of working the yeast works quicker and a bread is produced which will remain fresh and sweet for a longer period than bread made in the ordinary way.—A. G. B.

An Improved Preparation of Food for Animals, Game, and Poultry. E. Wylam, London. Eng. Pat. 14,417, September 12, 1890. 4d.

The claim in this patent is for incorporating the nuts the product of *Arachis hypogea* L. (Nat. ord. Leguminosae) with any other ingredients which are usually used in making food for dogs, &c. One part of the nuts by weight to 16 parts of the other ingredients as a whole by weight, is recommended.—A. G. B.

Improvements Relating to the Preservation of Bread and similar Substances, and to Apparatus therefor. G. F. Redfern, London. From E. Schramm, Charlottenburg, and A. Chechong, Berlin, Germany. Eng. Pat. 16,362, October 14, 1890. 6d.

The bread is packed whilst hot in tins, which are afterwards hermetically sealed. The packing is preferably performed in an air tight chamber continuous with the oven, in which case the tins are first sterilised by drawing the hot air from the oven through them. Otherwise the loaves are placed in the tins whilst hot, the air is pumped out of the tins and sterilised air, or air saturated with moisture, allowed to enter before the opening is sealed.—A. G. B.

Improvements in Baking Powders and like Preparations. B. Willeox, London. From "The Rumford Chemical Works," U.S.A. Eng. Pat. 17,215, October 28, 1890. 6d.

It is customary in the preparation of baking powders to dilute the bicarbonate of soda and dry acid or acid salt used with some inert substance such as starch, flour, or other dry powder. Corn-starch is the substance usually used as a diluent. Baking powders mixed with corn-starch deteriorate when exposed to the air, owing to the absorption of moisture which causes a reaction between the alkaline carbonate and the acid. The invention is for the purpose of obviating this deterioration by the use of a diluent consisting of a salt of a fatty acid with an inorganic base. Among such salts calcium stearate is the preparation instanced as one of those suitable for a diluent.—H. S. P.

New or Improved Corn Products, and Process for Manufacturing the same. B. G. Hudnut, Indiana, U.S.A. Eng. Pat. 17,427, October 31, 1890. (Internat. Conv. April 5, 1890.) 6d.

The corn is made into hominy and separated from offal. The hominy is dried, cleaned, and partially cooked with steam. One of two processes is then followed; the partly cooked hominy is either passed through rolls and afterwards dried, in which case the product is in flakes, or first dried and then passed through the rolls, the product being granular. The products are used for food or brewing.

—A. G. B.

New or Improved Corn or Grain Products and Method for Manufacturing the same. W. P. Thompson, Liverpool. From E. Lankoff, Detroit, U.S.A. Eng. Pat. 19,457, November 29, 1890. 4d.

The cereal in its dry, raw, or normal condition is crushed into coarse meal, the hulls and other impurities removed, and the meal subjected to a "drawing compression," without heat, between smooth rollers, one of which travels faster than the other. The resulting product is a light, thin, curled film with a large surface. It has heretofore been necessary to steam, soak, or soften the cereal meal, whereby some of the strength thereof has been lost; moreover, when the rollers are hot the surface of the crushed cereal is so cooked and glazed as to be less soluble. By this new method the maximum solubility is ensured.—A. G. B.

(B.)—SANITARY CHEMISTRY.

The Treatment of Sewage. G. E. Davis.

See pages 221—227.

The Analysis of the Air of Large Cities. Industries, 10, 1891, 91.

THE question of air pollution is being taken up in earnest in Manchester. Certainly the smoky condition of the atmosphere of our large cities has, in conjunction with fogs, been brought prominently forward during the long frost, and any movement which has for its object the minimising of the evil has our hearty support. The late Dr. Angus-Smith, in his book on "Air and Rain," gave a *résumé* of the large amount of work he had done in connexion with air analysis, but not much attention seems to have been given to the subject in recent years. Much remains to be cleared up as to the origin of fogs, although a good deal of attention has been paid to the matter by Aitken, whose papers have appeared in the *Philosophical Magazine*. It was thought, therefore, that a systematic series of analyses, carried out at different points of a large city at the same time, would give valuable information as to the chief causes of pollution, and to this end a chemical sub-committee has been appointed by the Town Gardening Section of the Manchester Field Naturalists' Society. The committee consists of Dr. Bailey, Dr. Cohen, and Mr. P. J. Hartog, B.Sc., of the Owens College Chemical Staff, and Dr. Tatham, Medical Officer of Health for Manchester. A subscription list was opened to defray the cost of apparatus, &c., and about 200*l.*, the sum required, has been raised.

The analytical scheme is a very comprehensive one. The observations, which are to be made at seven different stations in Manchester and Salford, are intended to afford definite information on the following points:—

1. The composition of the air in densely populated as compared with thinly populated districts.
2. The relation between atmospheric impurities and prevalent sickness and mortality.
3. Amount and distribution of noxious ingredients specially injurious to plant life, *e.g.*, sulphurous acid.
4. The extent to which smoke and noxious gases are due to (a) dwellings; (b) factories.
5. Nature of fog, and the chemical character of the air during the prevalence of fogs.

At a meeting of the Society on the 7th instant Dr. Bailey reported that their investigations had been commenced. They had found, he said, that the snow carried to the ground large quantities of sulphuric and hydrochloric acids, and also some of the elements of sewage. The depositions on leaves collected at the various observing stations were in amount directly as the population, and the greatest injury to plant life was found to be due to the emanations from dwelling-houses. They estimated that, in one day, two tons of "blacks" and 3 cwt. of sulphuric acid were deposited per square mile of the city area. The above figures are sufficient to show that much interesting and valuable information may be looked for when the final report of the committee is issued. On similar lines, a committee, with which the names of Professor Oliver, of University College, London, and Mr. Scott, the botanist, are associated, has been appointed in London, the initiative being due to the Royal Horticultural Society.

PATENTS.

An Improved Method of Nitrogenising Substances in the Manufacture of Manures and for other Purposes. H. Fawson, Buckingham. Eng. Pat. 20,076, December 13, 1889. 8*d.*

See under XV., page 261.

Improvements in Furnaces for Burning Tan and other Refuse Material. C. A. Brown, Exeter. Eng. Pat. 1170, January 22, 1890. 6*d.*

See under I., page 239.

Improvements in the Treatment of Night-Soil and such like Noxious Matters, and in Apparatus therefor. E. W. Cracknell, Sydney, New South Wales. Eng. Pat. 17,687, November 4, 1890. 8*d.*

THE mixture of rubbish and night-soil is screened, disintegrated, dried and converted into pondrette. The larger substances and such as resist disintegration are burnt. All the machinery or chambers containing the same are connected by pipes to a central exhaust fan which passes the vapours and gases to the ash-pit of the furnace where they are consumed. The claims are for the arrangement and construction of machinery, and the method of collecting and burning noxious vapours; these are severally set forth in the drawings accompanying the specification, which must be consulted for details.—A. G. B.

(C.)—DISINFECTANTS.

Paris Green as an Insecticide. Standard Agricultural Report, Mar. 10, 1891.

ONE of the most important sections of Miss Ormerod's Annual Report is that which describes the results of experiments with insecticides carried out by a committee appointed among fruit-growers in the Evesham district. The most effectual agent for the destruction of caterpillars was Paris green, a double salt of arsenic and acetate of copper, containing about 28½ per cent. of arsenic and over 32 per cent. of copper, and, therefore, a strong poison which should be used with great caution in proper dilution. This insecticide has long been a favourite in America, but has not been tried extensively in this country. The Evesham fruit-growers who used it last year are almost unanimous in favour of it, and although it is a pity that some less dangerous preparation has not proved equally effectual in killing caterpillars, the need of destroying these rapacious creatures is so urgent that fruit-growers cannot afford to be very particular as to the means adopted for getting rid of them. Provided the Paris green is used in the form of paste, and not in that of powder (which is likely to be inhaled by the person using it), and properly diluted, it may be applied without danger. One ounce of the paste should be diluted with 10 gallons of water for plum trees, and with 20 gallons for apples or pears, and applied before or after the blossoming period. This solution, sprayed over the trees, is fatal to caterpillars, and does not hurt the foliage, though it might injure the blossoms. Live stock should be kept out of orchards for a few days after the trees have been sprayed.

XIX.—PAPER, PASTEBOARD, Etc.

PATENTS.

An Improved Arrangement of Roasting Apparatus for the Incinerating of Black Liquor and Spent Soda Lye used in the Boiling of Esparto Grass or other Fibrous Matter. T. Goodall, Sunderland. Eng. Pat. 1087, January 21, 1890. 8*d.*

THE apparatus consists of two or more superimposed roasting beds or hearths upon which the black liquor or spent soda lye is roasted. At one end of the hearths are placed independent fuel grates also superimposed. These grates have independent flues communicating with one common main flue leading to the chimney, and these flues

are fitted with dampers in such a way that the flame and heated products of combustion may be led from any of the grates over the roasting hearths, finding their exit finally over one or more of the grates not placed in connexion with the roasting beds, before passing to the chimney. In this way the organic volatile matters evolved from the roasting hearths are completely burnt before entering the chimney flue. At the end of the roasting hearths farthest from the grates is built a burning off chamber. The partially roasted ash from the hearths is transferred to this chamber where it remains until completely burnt, the gases from this chamber passing away along with the gases from the hearths. Tanks containing the liquor may be placed over the top hearth or over the burning off chamber, in which tanks the liquor becomes heated and concentrated by the heat from the chamber and hearth, and from which by suitable pipes it may be fed into the roasting hearths. Or, by another modification, an additional flue may be placed at the end of the burning off chamber farthest from the roasting beds, and fitted with a damper so that the operation may be varied by leading all the gases from the beds over the material in the burning off chamber, whence they pass away by the end flue.—H. S. P.

An Improvement in Boilers used in the Manufacture of Paper Pulp. C. D. Davies, Manchester. From C. Kellner, Vienna, Austria. Eng. Pat. 2964, February 8, 1890. 4d.

INSTEAD of coating the inside of boilers used in the acid processes of manufacturing wood pulp with sections or segments of lead, the present inventor lines the boiler with an acid-resisting cement such as a mixture of Portland cement and sand.—E. J. B.

Improvements relating to the Treatment of Straw, Esparto Grass, and other Fibrous Materials for the Manufacture of Paper and other Purposes, and to Compounds therefor. E. Applegarth, London. Eng. Pat. 2832, February 21, 1890. 6d.

THE inventor prepares a compound by boiling together "caustic soda, boracic acid water, kerosene oil, or any other unctuous or spirituous product of petroleum, and animal fat or oil of vegetable oil." A suitable quantity of this compound is added to the caustic lye or other alkaline solution in which the straw or other fibrous material is boiled.—E. J. B.

Improvements in the Manufacture of Manilla Paper. J. B. Atherton, Huxton. From L. B. Beck, New York, U.S.A. Eng. Pat. 11,924, July 15, 1890. 8d.

THIS invention relates to a method of preparing Manilla paper which may be used for insulating electric wires.

The fibre is first cut into lengths of not more than $2\frac{1}{2}$ in. It is then opened out by a suitable machine, such as an "oakum devil," and packed tightly into an open wooden vessel fitted with a perforated bottom and steam pipe for heating. Here it is macerated with a solution of caustic soda for 20 hours or longer, if necessary until the fibres are easily separated by slight pressure. It is then gently "beaten" for five to seven hours, and the alkaline liquor removed by washing. The pulp is then made into paper without sizing, preferably on a cylinder machine.—E. J. B.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

Veratrine. S. Strauskey. Monatsh. 11, 482—483.

SOME years ago the author commenced an investigation of the alkaloid veratrine, which, since it was studied by Bosetti (Arch. fur Pharm. 1883, 81), has received but little attention; the results of his unfinished experiments are now published on account of the recent appearance of a paper by Ahrens (Ber. 23, 2700—2707; this Journal, 1890, 1060) on this subject.

Veratrine, obtained from Merck and purified by Schmidt and Köppen's method (Annalen, 185, 221) is very readily soluble in warm xylene and glycerin, and in cold aniline carbon bisulphide, ethyl acetate, acetone, chloroform, and amyl alcohol, but it is only sparingly soluble in hot light petroleum.

According to Bosetti, the commercial alkaloid is a mixture of crystalline veratrine with veratridine; the former is insoluble in water and is decomposed by alkalis into ceridine and angelic acid, whereas the latter is soluble in water and is decomposed by alkalis into veratrin and veratrum acid (melting point 179.5°). The author's experiments gave results completely in accordance with those obtained by Bosetti.

When the mixture of bases (veratrin and ceridine) obtained by boiling the alkaloid with alcoholic potash is fused with potash, methylamine and pyridine bases are produced. When veratrine is distilled with zinc dust, it yields a brown oil which seems to be a mixture of pyridine bases with a neutral compound which has an odour of, but does not show the reactions of, veratrol.—F. S. K.

**Communication from the Pharmaceutical Laboratory of the Botanical Garden of Brinitzorg (Java).* M. Greshoff. Ber. 23, 3537—3550.

CARRAINT, an alkaloid found in the leaves of *Carica papaya L.* may be obtained by extraction with alcohol, chloroform, or ether. In the latter solvent it appears to be more readily dissolved from the leaves than after it has been separated in the crystalline state. It occurs in largest quantity in the young leaves, from which 0.25 per cent. of the alkaloid may be obtained. From the solutions of its salts the alkaloid is completely precipitated by sodium carbonate; it is also insoluble in potash solution. It is precipitated by the following reagents:—Mayer's reagent and iodine solution (1 in 300,000); phosphomolybdic acid (1 in 75,000); picric acid (1 in 30,000); gold chloride (1 in 25,000); tannin and potassium sulphocyanide. No colourations are produced by strong mineral acids. It melts at 115° , and volatilises partly undecomposed.

It is a vegetable poison, which acts upon the heart. The fatal dose for *Bufo melanostictus schw.* (which is used in the place of a frog for physiological investigations) is 0.012 gm., that for a fowl 0.200 gm. With acids it forms well-crystallisable salts. The hydrochloride is soluble in water, and crystallises in beautiful shining needles. The base dissolves in 100,000 parts of water, and has a bitter taste.

Derrid, a tarry substance obtained from the bark of the root of *Derris (Pongamia) elliptica Benth.* is the active principle of the decoction used in Java for killing fish. It contains no nitrogen, and is not a glucoside. It dissolves readily in alcohol, ether, chloroform, amyl alcohol, &c., but very sparingly in water. It commences to melt at 61° , and decomposes at 160° . Fused with potash, sulcyllic and protocatechuic acids are formed. It has not been obtained in the crystalline condition, and its preparation in the pure state is very difficult. The roots contain about 2.5 to 3 per cent. of the tar. The alcoholic solution has a slightly acid

* For a more lengthy description of these researches, see "Eerste Verslag van het onderzoek naar de plantengestoffen van Nederlandsch-Indië." Batavia Land's Drukkery, 1890.

reaction, has an aromatic taste, and destroys the sensitiveness of the tongue for some hours. One part in 5,000,000 of water acts instantly on large fish.

Pachyrhizid, a substance closely analogous with *Derrid*, is obtained from the seeds of *Pachyrhizus angulatus* Rich. A decoction of this substance in 125,000 parts of water caused death in the case of *ophiocephalus javanicus* very quickly. It is unaccompanied by any tarry substance, and may be obtained in the pure state. Its solubility and melting point correspond with those of *derrid*.

Erythrina (*Stenotropis*) *Proteroi Hassk* contains an alkaloid in the bark, which is soluble in ether. The sulphate crystallises from the concentrated aqueous solution. With mercuric chloride, gold chloride, platinum chloride, potassium sulphocyanide, potassium dichromate, picric acid, iodine, and tannin, it forms precipitates. From the seeds of *Erythrina* (*Hypaphorus*) *subumbratus Hassk* another poisonous alkaloid has been separated.

Cassia glauca Lam contains a glucoside in its leaves.

The seeds of *Crotolaria retusa* L., and the seeds and leaves of *Crotolaria striata* L., contain an alkaloid, and the leaves of the first named contain a large quantity of indican.

The seeds of *Millettia atropurpurea* Benth contain a glucoside, the properties of which are somewhat similar to those of saponin.

The bark of *Acacia tenerrima* Jugh contain an amorphous alkaloid of bitter taste soluble in ether and chloroform.

From the leaves of *Albizia saponaria* Bl., cathartic acid has been separated; the seeds and bark contain saponin.

Several members of the natural order *Pithecolobium* Endl. contain alkaloids.

The bark of *P. bigeminum* Mart contains 0.8 per cent. of an amorphous non-volatile alkaloid, which forms crystalline salts. It is readily soluble in chloroform and ether, and is precipitated by alkalis from the solutions of its salts as a heavy yellow oil. Shaken up with water, it forms a milky liquid, which possesses a burning taste, and reacts with the usual reagents for alkaloids. Mayer's reagent gives a definite reaction with a proportion of 1 in 200,000, and picric acid gives a definite reaction with 1:100,000. Subcutaneously injected to fowls, it rapidly stops the heart's action, and fish are destroyed in a solution of 1:400,000. It also acts strongly on the mucous membrane.

The bark of *P. saman* Benth contains a body very similar to sapotoxine.

The seeds, bark, and leaves of *Melodinus laevigatus* Bl. contain an alkaloid, which occurs, however, principally in the seeds. It reacts readily and in minute quantity with the usual alkaloid reagents, and with Erdmann's and Fröhde's reagents, potassium dichromate, chlorous acid, &c.; it dissolves, forming a beautiful green solution, which changes to deep blue, and finally an orange coloration. The alkaloid is decomposed by warm dilute mineral acids, and is poisonous.

From the bark of *Leuconotis eugeniaefolia* Dec. a crystalline alkaloid may be separated, which is soluble in ether, is a fairly strong poison, and reacts with the usual alkaloid reagents.

From the bark of *Rauwolfia canescens* W. 0.4 per cent. of an alkaloid has been separated with ether. A blue-fluorescing substance has also been obtained from the same source. The alkaloid gives a blood-red coloration with nitric acid, which is a beautiful and delicate reaction.

Other members of the family *Rauwolfia* family *R. serpentina*, *R. trifoliata*, *R. spectabilis* and *R. madurensis*, also contain the same alkaloid.

In the bark of *Hunteria Corymbosa* Rorb. a crystalline alkaloid is present, which forms crystallisable salts, reacts delicately with the usual alkaloid reagents, and is specially characterised by giving a blue coloration with Erdmann's and Fröhde's reagents. It has a strong paralyzing action, and a solution 1:10,000 has a sharp burning taste.

A crystalline alkaloid is present in the bark of *Pseudo-chrosia glomerata* Bl. It is soluble in ether, and possesses poisonous properties. There is also a blue fluorescing substance present.

From the bark of several varieties of the (Javan) *Ochrosia*, *O. Lactaria acuminata*, *Akeringx* and *Coc-*

cinea, three alkaloids have been separated. (1.) Soluble in ether, colourless and crystalline, and acts on the heart. (2.) Insoluble in ether, soluble in amyl alcohol, and which may be separated by means of its mercuric chloride salt. (3.) The alkaloid which is also found in the varieties of *Rauwolfia*, *Pseudo-chrosia*, *Kopsia* Bl., *Alstonia*, and *Voucanga* (*Orchippeda*) *Fatida*, and which crystallises in brownish yellow plates. It dissolves in dilute acid, forming an intense brown coloured solution. It is readily soluble in chloroform, less soluble in ether, which solution has a beautiful blue fluorescence, and reacts very delicately with metallic salts and other alkaloid reagents. This alkaloid is present in the seeds of *Kopsia flavidia* Bl.

The bark of *Voucanga* (*Orchippeda*) *Fatida* contains, besides the alkaloid just named, a second alkaloid, soluble in ether.

The kernel of the seeds of *Cerbera Odollam* Hamilt contains an active principle, *Cerberin*, which is neither nitrogenous, nor is it a glucoside. It crystallises well, is insoluble in water, soluble in alcohol, chloroform, glacial acetic acid, and in "80 per cent." ether. It melts at 165°. With sulphuric acid it gradually forms a beautiful violet colour; has a burning but only slightly bitter taste, and is very poisonous.

From several members of the natural order *Lawaceae* an alkaloid, *Laurolaurine*, has been separated. It is readily soluble in chloroform, less so in ether; sodium carbonate precipitates it, whilst excess of sodium or potassium hydroxide redissolves it. It is precipitated by the usual alkaloid reagents. The freshly prepared alkaloid commences, after a few days, to crystallise out in stellate groups of needles. Very small quantities of the base form a dark indigo blue solution with Erdmann's reagent. With sulphuric acid it forms a weak rose-coloured solution, with nitric acid a red-brown coloured one. Its toxicological action is very similar to that of strychnine.

Hydrogen cyanide has been found either free or combined in *Gymnema latifolium* Wall., in *Pygma parviflorum* T. et B., and *P. latifolium* Miq., in the fruit of *Lasia zollingeri* Schott, in the leaves of *Cyrtosperma Merkurii* Hassk., in the leaves, seeds, and fruit of *Pangium edule* Reinw., and in several varieties of *Hydnocarpus*.—J. W. L.

German and Turkish Rose-Oils. Poleck. Ber. 23, 3554—3555. (Compare this Journal, 1891, 63.)

On fractional distillation German rose-oil yields at first about 5 per cent. of ethyl alcohol, but no trace of terpenes. When free from stearoptene the bulk of the oil distils over between 110° and 120° C. under a pressure of 14 mm. The eleoptene thus obtained boils at 215° C. Turkish rose-oil behaves similarly. Both eleoptenes are slightly levo-rotatory and have the following specific gravities: that from German rose-oil, 0.8837 at 11° C.; from Turkish, 0.8813 at 12° C. Their composition is expressed by the formula $C_{10}H_{15}O$; no body of the formula $C_{10}H_{20}O$ could be detected. The substance $C_{10}H_{15}O$ is a primary alcohol possessing two ethylene linkings. By oxidation the corresponding aldehyde, $C_{10}H_{13}O$, and acid, $C_{10}H_{11}O_2$, are obtained. Phosphorous pentoxide and zinc chloride abstract water from the eleoptene and convert it into a mixture of two terpenes, of which the higher boiling point one exhibits strong dichroism when the temperature of dehydration is allowed to exceed 0° C. Strong oxidising agents convert the eleoptene into acetic, formic, carbonic, and oxalic acids, and a trace of some higher carbon acid. Chemically speaking, the volatile portion of rose-oil closely resembles geraniol, which Semmler obtained from Indian geranium-oil (this Journal, 1890, 889, 1145).—H. T. P.

Indian Geranium-Oil; Geranialdehyde and Geranic Acid. E. W. Semmler. Ber. 23, 3556—3557.

By oxidation with bichromate mixture geraniol is converted into geranialdehyde, and from the latter geranic acid is best prepared as follows: 13.5 grms. of silver nitrate are precipitated with baryta water, the precipitate is well washed and treated with ammonia until only very little

is left undissolved. The ammoniacal solution, measuring about 500 cc., is gradually added to an emulsion of 6 grms. of geranialdehyde in 500 cc. of water, about two hours being taken for the operation. The mixture is then slightly acidified with phosphoric acid and steam-distilled. The distillate is mixed with an excess of soda and evaporated to dryness. The residue is extracted with boiling absolute alcohol, the alcoholic solution is filtered and evaporated to dryness. Finally the residue is redissolved in water and treated with silver nitrate, which precipitates the insoluble silver salt of geranic acid, $C_{10}H_{17}O_2 \cdot Ag$. The free acid forms a thin oil, the properties of which will be described in a later paper. (Also see this Journal, 1890, 889, 1145.)

—H. T. P.

A Phenol-Sulphonic Acid derived from Camphor.
P. Cazeneuve. *Compt. Rend.* **111**, 743—745.

The author has recently described a neutral compound of the composition $C_9H_7O(OH)_2 \cdot SO_2$, obtained by treating monochlorocamphor with sulphuric acid (*Compt. Rend.* **110**, 749 and 961; this Journal, 1890, 647 and 853), and named amethylecamphophenol-sulphonic, because in its formation from camphor one methyl group is eliminated.

An acid, which the author calls *Amethylecamphophenol-sulphonic Acid*, $C_9H_7O(OH)_2 \cdot SO_3H$, and which is isomeric with the sulphonic, has now been obtained.

Amethylecamphophenol-sulphonic acid is a colourless acid syrup and behaves in some respects like tannic acid; it precipitates gelatin, quinine, cinchonine, brucine, and strychnine (but not morphine) from their solutions, and it reduces boiling solutions of the chlorides of gold and platinum, and also ammoniacal solutions of silver nitrate.

Improved Means and Appliances for the Production of Pure Carbonic Oxide Gas. T. Williams, London. Eng. Pat. 19,096, November 27, 1889. *8d.*

This is an improved arrangement of tanks, pipes, and machinery with an improved vacuum pump so as to enable pure carbon monoxide to be produced automatically and continuously from coal, coke, or other fuels; and if desired also the separation of hydrogen from carbon monoxide. Cuprous chloride is used to absorb the gas, the solution being re-utilised after expelling the carbon monoxide. The flow of the liquid solution is controlled by the pressure of the gas.

The gases from certain fuels require the use of salts of iron to ensure the efficient operation of the cuprous solution.

The specification is accompanied by drawings.—D. A. S.

Improvements in Obtaining Oxygen Gas from Atmospheric Air. A. Longsdon, London. From F. Salomon, Essen, Germany. Eng. Pat. 6553, April 29, 1890. *4d.*

The process consists "in heating a mixture of lead monoxide and alkaline earth, lime, for example, to a red heat in a retort, whilst air is passed over it. Oxygen is absorbed, and lead peroxide and plumbate of lime are formed. On passing carbonic acid gas over this, after the temperature has been allowed to fall to a certain point, oxygen is given off and the carbonic acid is absorbed. At first the oxygen given off is nearly pure. Afterwards some carbonic acid passes off with it, and this is removed by absorbing it with lime or carbonate of soda. The mixture of calcium carbonate and lead monoxide remaining in the retort is then reheated and treated with air, when the carbonic acid is expelled and oxygen again absorbed. Or the carbonic acid can be expelled with a mixture of air and steam. The greater part of the carbonic acid can be recovered for use again. Other metallic oxides, as, for instance, the oxides of manganese, may be used instead of lead monoxide, but the expulsion of the oxygen is not so easy as in the case of the lead combination.—H. S. P.

XXII.—EXPLOSIVES, MATCHES, Etc.

Siliceous Earths in Barbadoes. Board of Trade Journal.

In the middle portion of the Oceanic series beds of white Radiolarium earth occur, which are of exceedingly light specific gravity, and are almost purely siliceous. Such beds occur at Springfield, on Jones River estate, on Melvin's Hill at Mount Hillaby, and below the Spring estate. This earth is now in use as a boiler covering or felting through the British West Indies and in the most important works of British Guiana. The writers are aware of the existence of extensive deposits of similar material elsewhere in the West Indies.

Another use for these siliceous earths is as a substitute for kieselguhr in the manufacture of dynamite, and the characters of some of the Barbadian samples appear to be admirably suited for this purpose. A third use to which these light siliceous earths can be put is the preparation of polishing powders, and their freedom from all gritty matter makes them peculiarly suitable for this purpose.

They might also be used in the manufacture of sodium silicate on account of the easy solubility of the silica they contain. Lastly, they have been used with considerable advantage for accelerating the filtration of saccharine liquids in filter presses.

PATENTS.

An Improved Machine for Compressing Gunpowder into Cartridge Form. W. E. Flint, Wandsworth, and H. J. Michell, Chiswick. Eng. Pat. November 15, 1889. *1s. 1d.*

The machinery or apparatus constructed according to this invention acts throughout in all its operations in an automatic and continuous manner. "The powder passes from a hopper to a measure, the measure at the proper time delivers the powder through passages into a pressing chamber, the bottom of which has been closed by the rising of an underneath plunger; an upper plunger then descends a set distance and subjects the powder to a slight vertical pressure and regulates the length of the form to be produced; the pressing chamber (the sides of which are formed of moveable jaws), then closes in and subjects the contained powder to great lateral pressure; the jaws then begin to open and the lower plunger descends carrying the formed pellet on top, from whence it is swept into a suitable receptacle."

The specification is copiously illustrated by drawings.

—W. M.

Improvements in the Treatment or Preparation of Nitrate of Ammonium. "The Rohrrite Explosives Company, Limited," London; C. Roth, Charlottenburg, Germany; and W. J. Orsman, Gathurst. Eng. Pat. 20,101, December 13, 1889. *4d.*

To prevent the absorption of hygroscopic moisture by ammonium nitrate, the crystals of that salt are dried by heating to 80° C., and a solution of nitrocellulose "in the various nitro- and chloro-nitro compounds of benzene or of the benzene series of hydrocarbons and their derivatives" is then poured over them, the mixture thoroughly stirred and allowed to cool. This treatment is especially advantageous when the ammonium nitrate is used in the manufacture of explosives.—H. S. P.

Improvements in the Manufacture or Separation of Ammonium Nitrate and Sulphate or Chloride of Sodium and of Potassium. C. Roth, Charlottenburg, Germany. Eng. Pat. 858, January 16, 1890. *6d.*

AMMONIUM nitrate is prepared from equivalent quantities of ammonium sulphate and potassium or sodium nitrate, either by heating the aqueous solution of these salts or by melting them at a temperature below that at which ammonium nitrate dissociates. If the aqueous solution be heated to a temperature above 110° C. until practically all the water is driven off (110° C. being the temperature at which a solution of ammonium nitrate in an equal weight of water boils), or when the salts are heated in the absence of water and the melt maintained at a temperature between 160° and 200° C.,

sulphate of potassium or sodium, as the case may be, separates out in the solid form and settles to the bottom of the melt, whilst a liquid layer of ammonium nitrate remains above, which can easily be siphoned off, or otherwise removed. A solution of ammonium nitrate in an equal weight of water, at a temperature of 110°C ., is only capable of holding in solution 15 per cent. of sodium sulphate and 10 per cent. of potassium sulphate, and the solubility of these substances in ammonium nitrate decreases as the temperature is raised, until at 200°C . (at about which temperature ammonium nitrate decomposes) only traces are held in solution. Ammonium chloride may be similarly used instead of ammonium sulphate, but its greater cost makes it less advantageous.—H. S. P.

Improvements relating to the Manufacture of Nitrocellulose or Pyroxylin. H. H. Lake, London. From G. M. Mowbray, North Adams, Mass., U.S.A. Eng. Pat. 20,978, December 23, 1890. 4d.

THE inventor uses, as raw material, cotton rags, cotton lint from cotton seed hulls, and other materials, instead of fine pure unsized cotton tissue paper, and first steeps it in a bath of a salt, preferably a nitrate, and then passes it between rollers and slowly dries it. The salt crystallises in the cells of the fibre, and this action opens up the cells so that when the material is subsequently immersed in the acid bath nitration takes place more rapidly, and is effected at less cost than by the present process. It is pointed out that, although a nitrate is preferred "any salt crystallised, or even water crystallised by freezing, in the cells of the fibrous cellulose, facilitates nitration by rendering the inner walls of the cellular tissue more readily accessible to the acids of the immersion bath."—W. M.

XXIII.—ANALYTICAL CHEMISTRY.

APPARATUS.

Extraction Apparatus. O. Henzold. Zeits. Anal. Chem. 30, 1891, 15—16.

AFTER noting the difficulty of getting suitable corks for the ordinary Soxhlet extraction apparatus wholly free from

MODIFIED SOXHLET EXTRACTOR.

matter soluble in ether, and taking into account the inconvenient tendency of the syphon in some cases to run uninterr-

mittently, the author describes the apparatus shown in the figure.

The substance to be extracted is placed in the upper bulb without an enclosing paper cartridge, and rests on the plug of wadding *b*; *d* is another plug of wadding, and between them is a layer of animal charcoal *c*. The ethereal extract is thus compelled to pass through an efficient filtering medium before reaching the syphon. This latter is of the form commonly used with the Soxhlet apparatus, but has its upper bend connected with the main tube by a piece of tubing *a* constricted to a diameter of about 1 mm. This is designed to prevent the continuous syphoning mentioned above as a frequent failing of apparatus of this kind.

The lower end of the syphon discharges on to a folded filter *e* to ensure the removal of particles that may have escaped the upper filtering arrangement.

The apparatus is well adapted for such purposes as the extraction of fat in milk.—B. B.

Apparatus for Fractional Distillation. Greiner and Friedrichs. Zeits. Anal. Chem. 30, 1891, 17.

THE apparatus (three forms of which are illustrated) is designed to provide a means of regulating the cooling of

APPARATUS FOR FRACTIONAL DISTILLATION.

the vapour of a liquid to be fractionated. To this end in all three forms a wide tube is carried through the bulbs of the deplegator so that a current of air is induced in and flows along it, cooling the contents of the bulbs. The cooling effect can be controlled by regulating the draught. The forms are functionally identical, as far as their fractionating action is concerned, but those shown in Figs. 1 and 2 can also serve as supports for the fractionating flask, if fitted with heavy stands as illustrated.—B. A New Method of Distinguishing between Arsenical and Antimony Mirrors. G. Denigès. *Compt. Rend.* **111**, 821—825.

THE author draws attention to the use which may be made of the arsenic molybdate reaction as a confirmatory test of the presence of arsenic in the mirrors formed in Marsh's test. A pure antimony mirror will give no reaction, whilst phosphorus cannot be present in such a mirror. The author directs that the metallic mirror be treated with a few drops of pure nitric acid, which should be warmed to complete the oxidation to arsenic acid. Four or five drops of an acid solution of ammonium molybdate are then to be added, when the formation of the characteristic yellow crystals will follow if arsenic be present even to the extent of $\frac{1}{1000}$ of a milligramme. The crystals may be further identified by examination under a microscope with polarised light.

Estimation of Oxygen in Gas Mixtures. L. L. de Koninck.
Zeits. angew. Chem. 1890, 727—728.

As an absorbent of oxygen the author uses a solution of iron protosulphate prepared in the following way:—

Three aqueous solutions are first made, as follows:—

- A. 40 grms. of crystallised ferrous sulphate.
- B. 30 grms. of Seignette salt (sodium potassium tartrate).
- C. 60 grms. of potassium hydrate.

Each of these solutions is made up to 100 cc. 1 vol. of A. is then added to 5 vols. B.; a white precipitate of hydrated ferrous tartrate forms, which immediately dissolves on the further addition of 1 vol. of C. If the Seignette salt and potassium hydrate are first mixed together and then added to the ferrous sulphate a clear solution is not obtained.

The clear solution prepared as above is yellowish, in contact with the air it turns green owing to the formation of iron protosulphate, and on complete oxidation it again becomes clear.—H. S. P.

Analysis of Commercial Barium Hydrate. E. Hintz and H. Weber. *Zeits. Anal. Chem.* **30**, 1891, 24—29.

THE sample examined was found to contain as impurities barium carbonate, sulphate and thiosulphate, as well as traces of barium sulphide and sulphite. The last named was detected as follows.—On extracting the sample with water a residue consisting of barium sulphate, sulphite, carbonate and a portion of the thiosulphate present was obtained. This residue was boiled with sodium carbonate and a sulphite looked for in the filtrate by neutralising with acetic acid, and adding it to a solution of zinc sulphate containing very little sodium nitroprusside. The production of a red colour directly or on the addition of a solution of potassium ferrocyanide indicates the presence of sulphurous acid in small quantity.

The complete insolubility of barium sulphite was proved by precipitating the aqueous extract of the original sample with an alkaline lead solution (to remove the trace of sulphide present), and testing the filtrate for sulphite in the manner described above. This insolubility is turned to good account in the scheme for the quantitative analysis of the sample which was afterwards drawn up. The

presence of a thiosulphate was also recognised in an aqueous extract freed from sulphide by an alkaline lead solution, by means of silver nitrate. Armed with a knowledge of these facts the authors devise the following plan:—

1. *Determination of Barium Sulphide and Hydrate.*—About 20 grms. of the substance were dissolved in hot water freed from air by boiling in a weighed 500 cc. flask. After cooling, the flask was filled to the mark with cold water, weighed, the contents well mixed and allowed to settle for some time.

(1.) 50 cc. of the clear solution were withdrawn and weighed, acidulated with hydrochloric acid, precipitated with dilute sulphuric acid, and the resulting barium sulphate filtered off and weighed in the usual manner, giving the total amount of barium in a form soluble in water.

(2.) Similarly, 250 cc. were poured into a solution of pure potassium hydrate, to which a few drops of lead acetate had been added. Lead sulphide mixed with barium carbonate (from absorption of CO_2) separated out. It was filtered off, treated with a few drops of hydrochloric acid containing bromine, and the barium sulphate (formed by the reaction between the sulphuric acid produced by the oxidation of the lead sulphide and the barium chloride from the barium carbonate), collected and weighed, giving the quantity of barium sulphide present in the original substance. In such a determination the following precautions must be observed:—

(a.) As barium thiosulphate is present in the original aqueous solution, enough caustic potash must be used to prevent the formation of a precipitate of lead thiosulphate.

(b.) The barium sulphate finally weighed, may contain lead sulphate, particularly if there be much barium sulphide in the original substance. In such a case the precipitate must be fused with sodium carbonate and the total sulphuric acid determined in the aqueous extract of the melt after the removal of lead by means of carbon dioxide.

(3.) The filtrate from the mixed precipitate of lead sulphide and barium carbonate obtained in process (2) contains the portion of the total barium thiosulphate which has gone into solution. It is decomposed with hydrochloric acid containing bromine, barium sulphate equivalent to the barium thiosulphate present being precipitated; it may need purification from lead sulphate in the manner described in (2) (b).

The barium found as sulphide and thiosulphate deducted from the total quantity in the aqueous extract gives that present as hydrate.

II. *Determination of Barium Sulphate.*—Five grms. of the original substance were heated with dilute hydrochloric acid in a stream of carbon dioxide to expel all the sulphur dioxide. The whole contents of the flask were then transferred to a dish, evaporated to dryness, the residue taken up in water with a few drops of hydrochloric acid, the undissolved impure barium sulphate collected, washed, ignited, fused with sodium carbonate, and the sulphuric acid determined in the aqueous extract of the melt in the customary way.

III. *Determination of Barium Thiosulphate and Sulphite.*—Ten grms. were treated with water, the insoluble matter separated and washed. The aqueous extract was treated with alkaline lead solution as in I. (2) to remove sulphide (this precipitate can be obviously used instead of the portion taken in I. (2) to determine the barium sulphide), and the quantity of thiosulphate present determined in the filtrate as in I. (3). In the residue insoluble in water are only barium sulphate, sulphite, and carbonate, and that part of the barium thiosulphate that did not dissolve in water. It is placed in a flask fitted with a cork perforated by two holes, by one of which the flask is connected with an upright condenser at the upper end of which are two Peligot's tubes filled with hydrochloric acid containing bromine; a tube in the other hole of the cork connects the flask with a second flask containing dilute hydrochloric acid; this second flask is con-

nected in its turn with an apparatus for generating carbon dioxide. The tube connecting the two flasks can be shifted up and down in the cork of the second one so that it can either dip into the hydrochloric acid which it contains, or not. At first this tube is placed so that it is clear of the acid, and carbon dioxide is passed through the whole apparatus; when the air is all expelled the tube is dipped into the acid and a portion of the latter driven over into the flask containing the insoluble matter. Sulphur dioxide is liberated and is absorbed in the bromine hydrochloric acid in the Peligot's tubes; to complete its expulsion the contents of the flask are afterwards boiled, a stream of carbon dioxide being maintained throughout the operation. The liquid in the Peligot's tubes (containing sulphuric acid formed from the sulphur dioxide) is evaporated on the water-bath, the residue dissolved in water, precipitated with barium chloride, and the resulting barium sulphate collected and weighed. The sulphur dioxide which is thereby estimated has been derived from barium sulphite only in part, the larger portion of it coming from the barium thiosulphate also present in the insoluble residue. The production of this portion, however, is accompanied by the liberation of a corresponding quantity of sulphur which remains in the flask with the insoluble matter. Accordingly hydrochloric acid containing bromine is added to the contents of the flask to oxidise this sulphur, the whole evaporated to dryness, taken up with dilute hydrochloric acid, the residue of impure barium sulphate filtered off, ignited, and purified by fusion with sodium carbonate as previously described. The resulting pure barium sulphate represents not only the extra atom of sulphur of the thiosulphate, but the barium sulphate present in the sample as such which has been already determined (II.). The difference between these two quantities gives the data for calculating the thiosulphate, whence the amount of sulphur dioxide that must be deducted from the total quantity liberated may be reckoned, and the true percentage of barium sulphite obtained.

IV. Determination of Barium Carbonate.—The operation was made in the usual apparatus; on account of the presence of sulphide and thiosulphate the decomposition was effected by a mixture of strong potassium permanganate solution and dilute nitric acid. A further precaution was observed by placing an absorption tube filled with pumice moistened with strong permanganate solution next the generating flask.

The particular sample examined according to this method gave the following results:—

Barium hydrate ($\text{Ba}(\text{OH})_2 + 8 \text{H}_2\text{O}$), 94.3; barium sulphate, 0.52; barium sulphite, 0.07; barium thiosulphate, 0.70; barium carbonate, 1.75; and barium sulphide, 0.04.

Apart from the determination of barium sulphate and carbonate, the whole analysis might be performed on one portion could an arrangement for filtering and washing with complete exclusion of atmospheric carbon dioxide be devised.

For the determination of the barium hydrate only, it suffices to treat 250 cc. of the solution taken as in I. (2) directly with hydrochloric acid containing bromine, filtering from the barium sulphate produced from the barium sulphide and thiosulphate, and estimating the barium present in the filtrate.

If the alternative method of determining the barium sulphide be adopted (as given under III.) the weight of barium sulphate corresponding to it can be deducted from the total amount of barium sulphate resulting from this oxidation of barium sulphide and soluble thiosulphate, giving thereby the quantity of dissolved thiosulphate.

The only cause of difference between the determination of the barium hydrate gravimetrically, and by titration, is due to the presence of barium sulphide—a negligible error in the case of the sample quoted above.—B. B.

The Analysis of Commercial Sodium Fluoride. E. Hintz and H. Weber. *Zeits. Anal. Chem.* **30**, 1891, 30–33.

The sample examined had a strong alkaline reaction and was proved to contain sodium carbonate, silica, sulphuric acid, chlorine, potassium, lime, magnesia, alumina, and ferric oxide as impurities. Apparently it had been prepared by

evaporating a solution containing excess of sodium carbonate, whence it was concluded that no fluosilicate could be present as it would have suffered decomposition under such conditions.

The following is the process of analysis approved by the authors after many trials:—

I. Determination of Silica and Fluorine.—

(a.) 2–3 grms. of the substance are weighed and dissolved in water, in a capacious platinum dish, with the aid of heat. Ammonium carbonate is added and the liquid heated, more of the reagent being added as it evaporates. The resulting precipitate is filtered and washed with ammonium carbonate solution; it consists of impure silica and is set aside.

Sodium carbonate and a solution of zinc oxide in ammonia are then added to the filtrate, which is evaporated in a platinum dish until all the ammonia has been driven off, when the mixed precipitate of zinc silicate and hydrate is filtered off. The filtrate is preserved for the determination of fluorine. The silica is separated from the precipitate by evaporating to dryness with nitric acid, collected, ignited together with the impure silica previously precipitated with ammonium carbonate, and weighed. It may be volatilised with hydrofluoric and sulphuric acids and the non-volatile residue deducted, but on account of the probable presence of lime which would be converted into sulphate, and thus cause too large a correction to be made, it is preferably fused with sodium carbonate, and determined in the aqueous extract of the melt by evaporation with hydrochloric acid.

(b.) In the filtrate from the precipitation of the silica with an ammoniacal solution of zinc oxide, the fluorine is determined by precipitating hot with calcium chloride, filtering the mixed precipitate of calcium fluoride and carbonate, washing, igniting in a platinum crucible, evaporating to dryness in a platinum dish with a slight excess of acetic acid, taking up in hot water, and filtering and weighing the undissolved calcium fluoride. The purity of the calcium fluoride can be ascertained by converting a portion into sulphate by evaporation with sulphuric acid; sulphuric acid as an impurity can be looked for in another portion.

II. Determination of Sulphuric Acid and Chlorine.—

About 20 grms. are heated with water, cooled and made up to 1 litre (without previous filtration).

(a.) After proper time for settlement has elapsed, a measured quantity of the clear liquid is drawn off, acidified with hydrochloric acid in a platinum dish, and the sulphuric acid present precipitated by barium chloride. The precipitate is filtered and washed in a platinum funnel, fused with sodium carbonate, and sulphuric acid determined in the aqueous extract of the melt in the usual way. This operation is, if necessary, repeated. The purity of the barium sulphate finally attained is verified by its weight remaining constant on evaporation with sulphuric acid.

(b.) A second portion of the clear liquid is acidified with nitric acid in a platinum dish, and precipitated with silver nitrate for the chlorine.

III. The carbon dioxide is determined as usual, save that decomposition is effected by a strong solution of tartaric acid.

IV. The bases are determined in the usual way, after decomposition of the fluorides by evaporation with sulphuric acid.

V. The water is determined by heating the sample in a stream of dry air, and absorbing the water given off in a drying tube.

VI. A portion of the silica of the sample examined was present as sand. It was determined by treatment with water, and extraction of the insoluble matter thus left with a solution of sodium carbonate and caustic potash, followed by treatment with dilute hydrochloric acid.

The result of the analysis is shown below:—

Sodium fluoride, 65.65 per cent.; sodium chloride, 0.74; sodium carbonate, 13.89; sodium sulphate, 1.96; potassium sulphate, 0.74; soda (as silicate), 1.50; silica (partly as sodium silicate), 10.11; calcium carbonate, 0.25; magnesium carbonate, 0.32; ferric oxide, 0.48; alumina, 0.17; and water, 3.97. Total, 99.78.—B. B.

On a New Volumetric Method of Analysis for Sulphurous Chloride. G. A. Le Roy. *Monit. Scient.* 1820, **36**, 1115-1116.

NORMAN, sulphurous chloride (sulphur monochloride), S_2Cl_2 , contains 47.41 per cent. of sulphur and 52.59 per cent. of chlorine. It is, however, able to absorb considerable quantities of sulphur or chlorine. It is largely employed in the manufacture of artificial and of vulcanised caoutchouc, and as no doubt the employment of a substance of constant composition is of importance to the manufacturer, a method of determining the percentage of sulphur and chlorine easily and rapidly would be useful.

Rose, in his *Traité de chimie analytique* (Vol. II., 790), gives the following method of analysis:—The sulphur monochloride is first oxidised with fuming nitric acid, and the sulphur is then determined as barium sulphate. Secondly, the chlorine is obtained by difference. The direct estimation of the chlorine in compounds of sulphur and chlorine is difficult and unsatisfactory.

Le Roy therefore proposes the following method.—The sulphurous chloride is weighed out in a tared flask or measured with an accurate pipette, and run into a dilute solution of pure soda (containing 19.37 grms. of Na_2O per litre—10 grms. of sulphur per litre) of which a known volume has been taken. The sulphurous chloride is decomposed; sodium chloride, hyposulphite, sulphite, sulphate, and sulphide being formed, and free sulphur separating out. On heating, the latter disappears rapidly. When the sulphur has disappeared and the solution has been cooled, hydrogen peroxide is added, and the mixture gently warmed to convert all the sulphur into sulphate. The excess of hydrogen peroxide is then driven off by ebullition. The excess of soda is then titrated with pure nitric acid (39.35 grms. of HNO_3 per litre) in presence of an indicator (litmus, methyl-orange), and after adding to the quantity of soda thus obtained, the quantity obtained in combination with the chlorine (calculated from a second experiment) and deducting the sum from the total soda used, the amount combined with the sulphur is obtained by difference, and the latter can thus be determined *u. ce.* of soda sol. n and 0.01 gram. of sulphur.

The neutral solution, which is free from sulphides and sulphates, is then titrated for chlorine with standard silver nitrate and potassium chromate, or with ammonium sulphocyanide and ammoniacal iron persulphate.

—E. W. T. K.

ORGANIC CHEMISTRY.—QUANTITATIVE.

On the Examination of Beer. A. Bertschinger. *Zeits. f. angew. Chem.* 1890, 665-671.

THE author was instructed by the Swiss Society of Analytical Chemists to draw up a report embodying a standard method for the examination of beer. This has been adopted by the Society with some modifications. The leading features are here given.

Definition.—Beer is a beverage made from barley malt, hops, yeast, and water by mashing and alcoholic fermentation. If any malt or hop substitute has been used, this must be particularly stated.

Appearance.—Beer must be clear, or at most but slightly opalescent.

Composition.—Beer should contain more extract than alcohol. The amount of fermentation should be at least 48 per cent., beer which contains more than 3 per cent. maltose should not be sold.

The mineral constituents must not exceed 0.3 gram. in 100 grms. beer. A larger amount of mineral matter would indicate the addition of salts for neutralising or some other purpose.

The acidity of a normal beer calculated as lactic acid should be between 0.2 and 2.7 grms. per 1,000 grms. beer; that is, should require between 1 and 3 cc. normal soda solution for neutralisation. A beer with higher acidity is to be considered acid, and one with less has probably been neutralised.

The nitrogen should be at least 0.3 per cent. on the original wort solids, and the *phosphoric acid* about the same. A less amount points to the use of some malt substitutes like sugar or starch.

The acetic acid should not exceed 0.6 gram. per 1,000 grms. beer, *i.e.*, should not require more than 1 cc. normal soda solution for neutralisation.

The glycerol should not exceed 0.4 per cent.

Preservatives.—Neither salicylic acid, nor boric acid, nor any compounds of these should be used, and not more than 11 mgrms. per 1,000 grms. beer of sulphurous acid should be present.

Colouring.—None should be used. Dark-coloured beers should derive their colour from the malt used.

Beer pressure apparatus.—Only apparatus using compressed carbonic acid should be employed.

The following tables give the results of a large number of analyses of Swiss and German beers.

SWISS BEER.

	Number of Analyses.	Maximum.	Minimum.	Mean.
Alcohol	312	5.87	2.61	4.12
Extract	312	9.85	4.48	6.65
Mineral matters	197	0.339	0.121	0.210
Acidity	189	0.313	0.072	0.162
Maltose	23	3.97	0.72	1.75
Nitrogen	33	0.095	0.015	0.073
Phosphoric acid	150	0.106	0.025	0.071

Appendix.—Method adopted by the Swiss Society of Analytical Chemists for the examination of beer.

The amount of alcohol and extract present is to be determined. The acids remaining in the beer after removal of the carbonic acid is to be expressed as lactic acid in parts per 1,000. The other constituents are to be expressed in percentages.

First, the smell, taste, colour, transparency, and microscopic appearance of sediment or turbidity should be noted. Next, the specific gravity, alcohol, extract and mineral constituents should be determined. Finally the nitrogen, phosphoric acid, maltose, dextrin, glycerol, acetic acid, sulphates, chlorides, carbonic acid, sulphurous acid, salicylic acid, boric acid and foreign bitters should be determined.

In determining the carbonic acid, this may all be removed from the beer by continued shaking and gentle warming to 35° C.

The specific gravity is determined at 15° C.

The alcohol is determined by distillation and calculated by Holzner's tables.

The extract is determined from the specific gravity of the beer freed from alcohol, by evaporation to one quarter its bulk. The determination may be controlled by evaporating to dryness 10–20 cc. beer mixed with a known weight of sand and drying in the water bath 5–6 hours.

The mineral constituents are estimated by ashing 10–20 cc. beer.

The acidity is determined by titration with $\frac{1}{10}$ normal alkali after removal of the carbonic acid.

The original extract is obtained with a fair approximation by adding together the weight of extract and twice the weight of alcohol.

The degrees of fermentation are calculated from the formula $100(1 - \frac{\text{extract}}{\text{original extract}})$.

The nitrogen is determined by Kjeldahl's process, in 50 cc. beer evaporated to 5 cc.

The phosphoric acid is determined in the ash by ammonium molybdate, or directly in the beer, after treatment with charcoal, by titration with uranium solution.

The maltose is determined by Fehling's solution.

The dextrin is determined in the same way after saccharification.

The acetic acid is determined by Landmann's method.

The carbonic acid is determined by the loss when heated, loss of water being prevented by a calcium chloride tube. Or by passing the gases evolved on boiling into baryta water and weighing the carbonate precipitated.

Boric acid is detected in the concentrated beer by its flame reaction.

Foreign bitters are detected by Dragendorff's method.

On the Revision of Constants employed in the Analysis of Fats and Oils. R. T. Thomson and H. Ballantyne.

See pages 233–237.

Notes on Vegetable Butter. F. Jean. Monit. Scient. 1890 36, 1116–1119.

The manufacture of a vegetable butter from the oils obtained from cocoa-nuts is commencing to be a pretty large business on the Continent, both in France and Germany. The manufacture of the vegetable butter according to Dr. Schlück's method depends on the treatment of the cocoa-nut oils with alcohol and animal charcoal, which removes the volatile and fragrant fatty acids of the aromatic oils and makes the oils perfectly white. The product thus obtained is a perfectly white mass, of the consistency of butter, and of a sweet, neutral, agreeable flavour, melting at 25 and remarkably free from any tendency to turn rancid. It contains 0.357 per cent. of water, 0.011 per cent. of mineral matter, and 99.632 per cent. of fatty matter.

Ordinary butter from cow's milk contains about 7 per cent. of butyric, caproic, capric, caprylic acids, &c., and these soluble acids only exist in traces in vegetable and in animal fats such as margarin; whereas vegetable butter resembles milk in containing about the same amount of soluble acids.

Experiments on its digestibility by various experimenters go to show that it exercises no harmful influence on the digestion. An experiment of the author seems to show that vegetable butter is not quite so digestible as butter, though more digestible than margarin and similar butters.

Though vegetable butter does not easily mix with butter, it will no doubt be employed as an adulterant. However, it seems as if there will be no great difficulty in detecting such fraud.

On saponifying a suspected butter and then liberating the acids by means of alcohol and sulphuric acid, the very characteristic odour of coccine ether will be obtained if vegetable butter be present. The fatty acids obtained from a mixture of even 10 per cent. of it with butter have an acid flavour and taste disagreeably of rancid cocoa-nut.

Since the percentage of soluble fatty acids in butter and vegetable butter are practically alike, their determination would practically lead to no result. Thus, 5 grms. of vegetable butter require from 29–30 cc. of decinormal alkali, whereas butter requires about 32 cc.

The determination, however, of the volatile acids by the Reichert-Meissel-Wollny method will serve to detect fraud, i.e. if pretty considerable quantities of vegetable butter have been added. Butter requires 27 cc. of decinormal soda, vegetable butter requires 7–8 cc. The fraudulent addition of margarin is more easy to detect, as this only requires 0.8–0.9 cc. of tenth-normal alkali.

A lowering of the melting-point, too, of the butter acids may help to indicate the presence of vegetable butter, as it melts at 27°, whereas butter melts at about 38°.

In the oleo-refractometer vegetable butter gives -59° , whereas butter gives -30° , so that this is a good test.

Further, the author finds that fats and oils, according to their kind, possess the property of absorbing a definite volume of acetic acid (of special density). Thus, butters absorb about 63.33 per cent., margarin about 26.66 per cent., and vegetable butter above 100 per cent., so that the presence of the latter in butter will raise the acetic acid absorbing power of a butter.

The results obtained are tabulated on page 275.

The Determination of Rosin Oil in Lubricating Oil.

L. Storch. Ber. d. oesterr. Gesellsch. z. Forder. d. Chem. Ind. 9, 93.

Ten to fifteen gms. of the lubricating oil is gently warmed with about five times its weight of 96 per cent. alcohol, in a small flask on the water-bath, shaken and then cooled. The alcohol is then decanted into a tared Erlenmeyer flask, 7 cm. high; the residue in the first flask is carefully washed with a little 90 per cent. alcohol, and the washing added to that already in the Erlenmeyer flask. The whole is then gently boiled on a water-bath, the flask being surrounded by a

broken beaker to prevent condensation. When no more alcohol is evolved, the residue is cooled and weighed (A). This is then treated with ten times its weight of 96 per cent. alcohol. The solution is treated in exactly the same way as the first solution, and the weight of the residue is (B).

The difference between the amounts of alcohol used in the two cases was evidently necessary in order to dissolve the remaining mineral oil in the second experiment. The amount of alcohol used in the second solution is thus a guide to the amount of mineral oil, which, together with the rosin oil is again dissolved. By subtracting the amount from the weight of the residue B, a weight is obtained which is a little less than the amount of rosin oil actually present; the true weight lies between the weight of residue B and the weight when corrected as above.—A. L. S.

Investigation of China Teas. P. Drorkovitz. Jour. Russ. Chem. Soc. 22, 558—568.

The author undertook to find out how far the price of tea depends on the percentage of theine and tannin in it. The results of his numerous analyses are shown in the following table:—

ANALYSIS OF CHINA TEAS OF THE FIRST CROP OF 1890.

Constituents of the Tea Dried at 100° C.

The higher numbers of tea in it are better ones and more expensive. The author's conclusion from this table is that "it is not on the absolute amount of theine in tea that the price of different sorts depends, but on the relative percentage of theine to the total amount of tannin and products of fermentation, and the greater this ratio the higher is the price of the tea, and the more regular the fermentation the better the tea.

The methods used in estimating theine and tannin are as follows:—

Determination of Theine.—Ten grms. of tea leaves are ground, and scalded three times with 200 cc. of boiling water for five minutes each time, after which the tea is boiled twice with 200 cc. of water until no colouring is observed; then the solution is washed with petroleum ether for removing the fat and brown colouring matter of tea. 600 grms. of the liquid (containing the extract from 6 grms. of tea) are acted upon by 100 cc. of caustic baryta (4 cc. $\text{Ba}(\text{HO})_2 + 100$ cc. H_2O); the sediment being immediately filtered off, 583 grms. of the filtrate (corresponding to 5 grms. of tea) are mixed with 100 cc. of 20 per cent. solution of common salt and subsequently gradually treated with 400 cc. of chloroform in three parts. On evaporating and drying the remainder at 100°C ., white needles of theine are obtained.

Determination of Tannin.—Löwenthal's method, viz., oxidising tannin with potassium permanganate (see also this Journal, 1890, 1157—1159) in presence of excess of indigo carmine until a yellow tint appears, proved to be unreliable for two reasons:—

(1.) The result of the analysis greatly depends on the way of adding the permanganate; the slower it is added the less of it is required; and

(2.) The difficulty of establishing the strength of permanganate solution by tannin.

To avoid the second difficulty the author has found 31.3 grms. of tannin (not 41.20 grms. found by Neubauer) to correspond to 63 grms. of oxalic acid. Thus, having prepared the permanganate solution, of which 130 grms. would answer to 100 grms. of pure 10 per cent. oxalic acid, and 20 cc. of the same to oxidise 25 cc. of indigo carmine solution (about 50 grms. of indigo carmine dissolved in a litre of water, treated with 50 grms. of sulphuric acid, and filtered), the author mixes 40 cc. of extract of tea (as above) with 500 cc. of water, 25 cc. of indigo carmine solution, and 25 cc. of 20 per cent. sulphuric acid, and added potassium permanganate as follows: 32 cc. at once, then 2—3 drops per second, and finally 1 drop per second, until the yellow tint appears. "The total amount of the permanganate added, which ought not to exceed 38 cc., reduced by that required for the oxidation of indigo carmine points to the amount of the products of decomposition of tannin in tea, or rather to the stage of fermentation of the tea."—N. W. T.

The Analysis of Soap. J. F. Schnaible. J. Anal. Chem.; Chem. Trade J. 1890, 7, 403, 8, 39—40.

In soap which has not been carefully made, there may exist more or less unsaponified fat or free alkali, as the case may be. Besides these variations the commercial soap often contains varying amounts of rosin, alkaline carbonates and silicates, borax, Glauber's salt, pearl ash, starch, flint, tale, sand, &c., complicating the analysis to a corresponding degree. In toilet soap there may be found glycerin, alcohol, sugar, colouring matter, &c., while medicated soap often contains phenol, sulphur, potassium iodide, and other medical substances. (See this Journal, 1887, 681.)

After a careful comparison of the many analytical methods proposed, the author has found the following to give good results:

Water.—For the determination of water the method of Loewe (Fresenius, Zeits. Anal. Chem. 19, 112) was employed with good results. From 80 to 100 grms. of the soap (which has been reduced to very fine shavings, and represents an average sample) is weighed out between watch glasses and heated in the air bath, at first from 60° to 70°C ., to avoid melting, then at 100 to 105°C ., till it possesses a constant weight.

In selecting the sample in this, as well as in all subsequent determinations, it is essential that an average specimen be

obtained, since the content of water in the different parts of the bar varies considerably. This is best effected by cutting away about one-third from the end, and evenly scraping the cut surface of the remainder until a sufficient amount is obtained for the analysis. (See this Journal, 1884, 307.)

Unsaponified Matter.—For the determination of unsaponified matter (Allen's Com. Org. Analysis, Vol. II.), the soap which has been dried in the manner indicated, is extracted in a Soxhlet extraction-apparatus with petroleum ether, which for this purpose should boil below 80°C . and should leave no residue on evaporation. After the extraction is complete, the "petroleum ether" is distilled off, the residue dried at 100°C . and weighed.

In a boiled, well-made laundry soap, there should be no unsaponified matter unless the same had been subsequently added. In addition to unsaponified fats, foreign matters are sometimes found in the petroleum ether extract, such as soft paraffin (so-called "Mineral Soap Stock"), waxes, hydrocarbon oils, phenol, &c. If waxes be present the dried soap should be extracted with boiling toluene, which dissolves them better than petroleum ether.

Total Alkali and Fatty Acids.—The dried soap thus freed from unsaponified matter is next dissolved in hot water, preparatory to determining the total alkali and fatty acids. A pure soap dissolves completely in hot water, and no ordinary product should leave more than a slight residue.

If the article examined be "scouring soap," the insoluble residue will be found to contain large quantities of fine sand, and sometimes tale. The residue, if appreciable, should be washed by decantation and eventually brought upon a filter with hot water, dried at 100°C ., and weighed, after which, if desired, it can be subjected to further examination.

To the aqueous solution is added an excess of semi-normal sulphuric acid, setting free the fatty acids which rise to the surface. The beaker or vessel in which the precipitation was effected is next cooled with ice-water. When the fatty acids (U.S. Dept. Agric. Chem. Div. Bull. 13 [4], 456) have solidified, it is best to decant the liquid, remelt with hot water two or three times to remove any enclosed mineral acid, again cool, filter and wash with cold water until the washings are no longer acid, as shown by litmus.

The filtrate from the insoluble fatty acids contains the total alkali now present as sulphate, the excess of sulphuric acid and any glycerin which may have been present in the soap, if saponification were effected in the cold. The acid liquid may further contain a small amount of soluble fatty acids. It is first titrated with semi-normal potash, using methyl orange as indicator (Allen's Com. Org. Analysis, Vol. II., p. 260). From the original amount of sulphuric acid added and the number of cc. of semi-normal potash required to neutralise the excess of the same, can be determined the total alkali of the sample. It is calculated as Na_2O .

After the liquid has been rendered neutral to methyl orange (which indicates the mineral acid), phenolphthalein is added and more potash is run in. The number of cc. of potash required for neutralising corresponds to soluble fatty acids and is calculated to caprylic anhydride—

in the absence of more definite knowledge as to their nature.

The solution is now concentrated and tested for glycerin, which may be determined by evaporating to dryness and extracting with ether-alcohol mixture (Chem. Zeit. 8, 1667), oxidising to oxalic acid by means of permanganate (Chem. Zeit. 9, 975; also this Journal, 1886, 392) (not always applicable). (Allen's Com. Org. Analysis, Vol. II., p. 290.) In soaps containing silicates of the alkalis (a not unusual constituent), the gelatinous silicic acid which separates on the addition of sulphuric acid, remains with the fatty acids on filtration. To separate the fatty acids from this, as well as all other impurities which may be present, the author found the following method effective:—

The funnel containing the filter with the fatty acids is placed in a small beaker and heated in an air-bath (Allen's method). As the filter dries, the fatty acids pass through it and collect in the beaker below, while all the impurities

(silicic acid, traces of silica, tale, &c.) remain behind on the filter. Of course it is necessary to wash the filter, which remains saturated with the fatty acids, with hot re-distilled alcohol or petroleum ether, or else exhaust in an extraction apparatus. The alcohol or petroleum ether is distilled off, and the residue treated in the same way as the main quantity of fatty acids.

In determining the fatty acids in a soap, it is frequently convenient to extract with ether in a separating funnel (Chem. News, 43, 218).

To do this the soap solution is placed in the funnel and shaken with sulphuric acid and ether. The separated acids are at once dissolved in the ether. The aqueous solution may be drawn off below, the ethereal solution washed with water, the ether evaporated, and the residue dried at 100° C. and weighed.

Some analysts recommend (Chem. News, 48, 67) melting the fatty acids (if soft) with a weighed amount of paraffin or stearic acid, as by this means a firm coherent cake is obtained, which can be easily handled. The cake is washed, dried and weighed, and the weight of paraffin deducted.

This method, however, is not applicable when it is desired to make a further examination of the fatty acids, to determine their origin; in this case it is better to extract with ether, as given. Since the fatty acids exist in the soap as anhydrides, and are weighed as hydrates, it is necessary to multiply the weight found by the factor 0.9, which gives the weight of fatty anhydrides.

The fatty acids, after having been weighed, may be titrated with semi-normal potash, and from these data may be ascertained what portion of the total alkali exists in combination with the acid as soap. (See also this Journal, 1885, 369, 1887, 389, and 1890, 1072.)

Free Alkali.—To determine the per cent. of free alkali (Allen's Com. Org. Analysis, Vol. II., p. 251) in soap, a separate portion is weighed out and extracted with neutral alcohol in an extraction apparatus. The caustic alkali is determined in the alcoholic solution by titrating with semi-normal hydrochloric acid, using phenolphthalein as indicator.

When, however, the soap contains unsaponified fat, as is frequently the case if made by the so-called "cold process," this method cannot be used, since in alcoholic solution unsaponified fat would be readily saponified by the free caustic alkali present.

In such a case the soap must first be dried in an atmosphere free from carbon dioxide at 100° C., the unsaponified matter extracted with petroleum ether, and finally the soap dissolved in alcohol and the free alkali determined in the alcoholic solution as before.

The carbonate of soda, silicate of soda, borax, and everything insoluble in alcohol, remains behind in the extraction tube, and may be dried at 100° C. and weighed. If considerable, it may be further treated as follows:—

First, it should be exhausted with boiling water. One half of the solution is then titrated with semi-normal hydrochloric acid, using methyl orange as indicator. The amount of acid required corresponds to carbonate, silicate, and borate. In this solution sulphates may also be determined, and starch and gelatin tested for. The other half of the solution is examined qualitatively for carbonate, silicate and borate. If there remain considerable residue insoluble in water, it may be dried at 100° C., weighed, and further examined. (See also this Journal, 1889, 123.)

Resin.—Resin is a very common constituent of soaps, the resins of alkalis having a similar action to soaps, and the cheapness of the material often suggesting a partial substitution of it for the natural fats and oils.

As a qualitative test for resin, Gottlieb's (Benedikt, Analyse der Fette u. Wachstern, p. 121) method is reliable and easily made.

The soap is dissolved in water and heated to boiling. A strong solution of magnesium sulphate is added until the fatty acids are completely precipitated. The magnesium resins remain in solution. After boiling two or three minutes, the solution is filtered and the hot filtrate acidified with sulphuric acid. In the presence of resin the liquid becomes turbid, due to the separated resin acids. The boiling should be continued for half an hour, to make sure

that the turbidity is due to the resin acids and not to volatile fatty acids.

Badford (Benedikt, Analyse der Fette u. Wachstern, p. 121) recommends as a qualitative test for resin the solution of the soap or mixed fatty and resin acids in 80 per cent. alcohol, and the addition of an excess of a solution of calcium chloride with ammonia to alkaline reaction. After cooling, the precipitate is washed and filtered. The filtrate contains the calcium salt of the resin acids, together with a slight amount of calcium oleate. It is now acidified with hydrochloric acid, the resin separates as a soft, gummy and viscous mass.

For the quantitative determination of resin, several processes have been recommended.

Gladding's method (this Journal, 1882, 205, and 1883, 480), which is based on the solubility of the silver resins in ether, is open to objection on account of the inaccuracy arising from the repeated transfer of the ethereal solution and the numerous readings to be taken, and also on account of the evaporation of the ether which takes place. Furthermore, Wright and Thompson have shown the correction for oleic acid, which Gladding introduces, to be not at all constant.

A very convenient method, and one which the author found to give good results, is that devised by V. Hahl and Stadler (Benedikt, Analyse der Fette u. Wachstern, p. 125).

0.5 to 1 gram. of the fatty acids is heated in a closed flask on the water-bath with about 20 cc. alcohol to complete solution. The acids are neutralised with alkali, using phenolphthalein as indicator. The alcoholic soap solution is then poured into a beaker, the flask rinsed with water, the solution diluted to 200 cc., and silver nitrate added to complete precipitation. The precipitate (consisting of the silver salts of the resin and fatty acids) must be protected from the sunlight. It is filtered, washed with water, dried at 100° C., and then extracted in a Soxhlet extractor with ether. The silver resins dissolve in the ether, while the silver salts of the fatty acids remain behind. The ethereal solution, as it leaves the extraction tube, should be yellow or light brown in colour, but not dark brown. It is filtered, if necessary, and the filtrate shaken with hydrochloric acid in a separating funnel. The resulting ethereal solution of the resin acids is filtered from silver chloride, washed with water, and the filter and the separator rinsed with ether, the ether distilled off, and the residue dried at 100° C. As the resin is weighed in the hydrated form, its weight must first be multiplied by the factor .9732 to obtain the weight of the anhydride. (See also this Journal, 1886, 392.)

It is frequently of interest to know the origin of the fatty acids of a soap which is, however, in many cases a problem not easily solved. The only clues are to be sought in the specific gravity, combining weight, melting and solidifying points, and iodine number of fatty acids.

Occasionally, fats, before being used in soap making, are bleached by various chemical agents, the most common of which are, perhaps, potassium bichromate and hydrochloric acid or sulphuric acid. When such a mixture is heated in bleaching, as is frequently the case, the bichromate, acting on the hydrochloric acid, liberates chlorine, and, under favourable conditions, the chlorine combines with the unsaturated acids present in the fats as glycerides, thus utterly destroying the value of the iodine number—the most definite index as to the origin of the fats.

Again, it frequently occurs that mixtures of two or more fats may be used, the combining weights, iodine number, and other properties of which closely approximate those of an individual fat, and so an erroneous conclusion may be drawn from an examination of such mixed fatty acids.

When, however, a mixture of two fats, in their natural state, without having undergone any bleaching or refining process, has been used, it is generally possible to ascertain, with considerable accuracy, the nature of the fatty acids by means of the iodine number, it having been found by actual experiment that the iodine number of a mixture of two fats corresponds within the limits of analytical error with theoretical numbers calculated for the pure fats. (See also this Journal, 1883, 479—480.)—O. H.

New Books.

FRESENIUS' QUANTITATIVE ANALYSIS. Vol. II. Translated by CHAS. E. GROVES, F.R.S. Part III. Price 2s. 6d.

This, the second volume of Mr. Groves' translation of Fresenius, commences on page 193, in the subject of "Acidimetry." On page 205 the subject of Alkalimetry is taken up, followed by the description of methods for the valuation and analysis of Chloride of Potassium, Sulphate of Potash, Nitrate of Potash, and Gunpowder. On page 228 commences a description of methods for analysing Tartar. Later on, pp. 230-240, are found methods for analysing Black Ash, Common Salt, and Salt Cake, pp. 241-248 being devoted to the subject of the analysis of Bleaching Powder or Chloride of Lime. Then follow methods for analysing Acetate of Lime, Limestones, Dolomites, and Cements, Clays and Native and Mixed Silicates. After these, Chromium Compounds and Zinc Compounds follow, and here the volume ends uncompleted.

ENCYCLOPÆDIC ENGLISH-GERMAN AND GERMAN-ENGLISH DICTIONARY. Uniform in plan and arrangement with Sachs-Villatte's French-German and German-French Dictionary. Giving the pronunciation according to the phonetic system employed in the method of Toussaint-Langenscheidt. Part First: English-German. By Professor Dr. ED. MÜLLER. Unabridged edition. Berlin: Langenscheidt'sche Verlagsbuchhandlung (Professor G. Langenscheidt). 1891. New York: The International News Company. London: H. Grevel and Co., 33, King Street, Covent Garden.

PART I. is now issued, in paper cover, large 8vo size, with Introduction and extending from A to A.L.O. Price 1s. 6d.

THE METALLURGY OF STEEL. By HENRY MARION HOWE, A.M. (Harvard), S.B. Volume I. Second Edition, Revised and Enlarged. The Scientific Publishing Company, 27, Park Place, New York. 1891.

THIS is a quarto volume, handsomely bound in brown cloth and gilt. The work is dedicated to Sir Lowthian Bell, Bart., F.R.S., as a token of the author's admiration. It contains Prefaces to the First and Second Editions, List of Errata, Tables of Contents, List of Illustrations and of Tables, and Subject-Matter extending over 385 pages, closing with an Alphabetical Index and Advertisers' Index. There are 232 excellent wood engravings and numerous tables. The matter is classified as follows:—Chap. I. Classification and Constitution of Steel. II. Carbon and Iron. Hardening, Tempering, and Annealing. Evidence that there are two conditions of Combination of Carbon with Iron. Effect of Carbon on the Physical Properties of Iron. Hardening, Tempering, and Annealing. Rationale of Hardening and Annealing. III. Iron and Silicon. IV. Iron and Manganese. V. Iron and Sulphur. VI. Iron and Phosphorus. Effect of Phosphorus on the Physical Properties of Iron. VII. Chromium, Tungsten, Copper. VIII. The Metals occurring but sparingly in Iron. IX. Iron and Oxygen. X. Nitrogen, Hydrogen, Carbonic Oxide. XI. The Absorption and Escape of Gas from Iron. XII. The Prevention of Blowholes and Pipes. XIII. Structure and Related Subjects. XIV. Cold-working. Hot-working. Welding. XV. Direct Processes. XVI. Charcoal-Hearth Processes. XVII. The Crucible Steel Process. XVIII. Apparatus for the Bessemer Process.

Appendix I. Special Steels. II. Anti-rust Coatings. III. Lead Quenching. IV. Direct Processes.

Trade Report.

TARIFF CHANGES AND CUSTOMS REGULATIONS.

ITALY.

Recent Customs Decisions.

Note.—Quintal = 220·4 lb. avoirdupois. Lira = 9 $\frac{16}{100}$ d.

The following decisions affecting the classification of articles in the Italian Customs tariff have been given by the Italian Customs authorities:—

Oxidised enamel colour.—Category 73*b*. Duty, 50 lire per quintal.

Aristol (chemical preparation).—Category 61. Duty, 10 lire per quintal.

Betha naphthaline.—Category 51*b*. Duty, 4 lire per quintal.

CANADA.

Grease for Soap Manufacture.

The *Canada Gazette* for the 31st January publishes an order of the Governor-General of Canada in Council, providing that under authority of section No. 248 of the Customs Act, the item No. 277, chapter 20, 53 Victoria, intitled "An Act to amend the Act respecting the Duties of Customs" is to be interpreted and to read as follows:—

Grease, rough, the refuse of animal fat, such as is fit only for use in the manufacture of soap, although the same is passed through a process of deodorisation. Provided that the same shall not be admitted free of duty except when imported by soap manufacturers for the manufacture of soap only, in their own factories, and in all cases of importation, on entry of such grease, the importer, when he claims the exemption from duty, shall swear to and subscribe the following affidavit:—

"I, _____, the undersigned importer of the grease mentioned in this entry, do solemnly swear that such grease is fit only for the manufacture of soap, that it is imported by me for that purpose, and will be, and all products thereof will be wholly used for that purpose only, and will be so used in my factory situate at _____ in the province of _____."

Customs Decision.

The following decision affecting the classification of copper in the Customs tariff of Canada has, according to the *Canada Gazette*, been recently given by the Canadian Board of Customs under the approval of the Governor-General in Council:—

Metallic copper, the exclusive product of Canadian ore smelted abroad and returned to Canada by the producers of the ores from which smelted, may, for one year from the 1st February 1891, be admitted into Canada under such regulations as the Minister of Customs may prescribe, and on payment of duty on the cost of smelting thereof.

MAURITIUS.

Customs Tariff.

Note.—Kilog. = 2·204 lb. avoirdupois; Hectolitre = 22 imp. gallons; Metre = 1·094 yds.; Rupee = 2s. (nominal value).

The following is a statement of the rates of Customs duty now levied on merchandise imported into the island of Mauritius:—

Note.—Under Ordinance No. 20 of 24th December 1890, a surcharge of 10 per cent. has been levied on import duties, except those on rice, salt fish or dried fish, wheat and wheat flour, dholl, lentils, wine in casks, salt beef and salt pork (salt pork does not include hams and bacon). The same to remain in force up to 31st December next inclusively.

EXTRACTS FROM DIPLOMATIC AND CONSULAR REPORTS.

DUTCH COLONIES.

Drugs, Soaps, and Perfumes.

By far the greater part of the chemicals used for hygienic purposes and by pharmacists in Java are of German manufacture. British industry, although otherwise quite capable of competing successfully, is left far behind here in consequence of the intimate connexions existing between the Dutch and Dutch-Indian medical men, pharmacists and scientists, and the manufacturing and scientific circles in Germany, where many of them have studied. The quinine used here in very large quantities against tropical fever is nearly all of German make. Paints are nearly all British, only white lead in powder being obtained from Germany, but aniline and other dyes are mostly German. In soap Germany tries to compete to some extent, but cannot do so successfully against the cheap English soaps, especially common yellow washing soap in bars from Liverpool. German soap dries too rapidly. The best toilet soaps are of French manufacture. In perfumery also the French easily maintain their lead upon the market, but the enormous consumption of eau de Cologne of all brands is supplied by Germany. Lately German firms have also tried to obtain a footing with other perfumes, but they found it very difficult to place their goods here at satisfactory prices.

Mineral Waters.

Almost without exception all mineral waters used here are imported from Germany. Apollinaris is the most favoured kind, but many other brands are also used. The consumption is large, and increases year by year, partly owing to the inferiority of the local drinking-water, partly because of the growing tendency to substitute a mixture of brandy and mineral waters as a beverage for beer, wine, or liqueurs.—*Chemist and Druggist*.

RUSSIA.

Mercury and Phosphorus.

Among the articles of export from Russia which are now beginning to attain a certain importance are quicksilver and phosphorus. Until quite recently Russia obtained all the quicksilver consumed by her from abroad, but since the commencement of exploitations of the mines of Bakhmut, Russian mercury is not only ousting the foreign article from the local markets, but it has become an article of export. In 1887, 7,803 poods of it were exported from St. Petersburg and Libau. In 1889, 3,150 poods of phosphorus were also exported.

Quicksilver.

The mercury mines of Saigewa, near the Nikitowka station of the Azof railway prove to be exceedingly rich. The deposits contain three layers of hydrargurous ore, the total quantity of ore containing metal being estimated at

12,000,000 poods. The ore is sprung by means of dynamite crushed by manual labour and by crushing machines, and finally roasted. In 1889, the yield of the mines was 10,202 poods of pure metallic quicksilver. In working the deposits, traces of former workings and abandoned pits are found, showing that these same mines have already been exploited in ancient times.—*Ibid*.

MISCELLANEOUS TRADE NOTICES.

NEW TANNING PRODUCT IN ANGOLA.

Sir G. G. Petre, Her Majesty's Minister at Lisbon, in a despatch to the Foreign Office, dated the 2nd February, says:—

"The *Official Journal* of the 31st January publishes a Royal decree dated the 28th, granting to Senhores Amado and Swart, merchants in Angola, the exclusive privilege for 10 years of exporting from the province of Angola, the district of Congo excepted, a new industrial product invented by them and extracted from a common tubercle which has not yet been scientifically classified for any industrial purpose. The use to which the product in question, of which no name is given, is to be applied, is that of tanning ("*curtimento*") of hides.

In a postscript Sir G. G. Petre adds: "The export duty on the product in question is fixed in the decree at 5 per cent. *ad valorem* when shipped to foreign ports, and at 3 per cent. *ad valorem* when sent to a Portuguese port."—*Board of Trade Journal*.

BRINE AT STAFFORD.

Boring and pumping operations have been going on for some time past in the neighbourhood of Stafford in connexion with the water supply, and a discovery of brine has now been incidentally made which may prove of considerable importance. Some 10 years ago the Stafford Corporation made an unsuccessful attempt to obtain a water supply by boring on Stafford Common. But after a great loss of money the boring had to be abandoned owing to a thick deposit of salt which was liquefied by the water, and rendered it impossible to obtain pure water from that site. The boring at Eason Moor, not far distant, a few years later revealed a similar obstacle, and the Corporation had also to abandon the measures on that side of the town. The Common site has recently been sold to a private firm. The boring was re-opened, and pumping commenced a fortnight ago. When the water had been reduced to 40 ft. below the surface, brine began to rise with from 17 to 25 degrees of saturation. The supply of brine is large, it being found impossible to reduce the head below 50 ft. from the surface by pumping at the rate of 320 gallons per minute. The brine is said to be the strongest yet discovered in Staffordshire. It is anticipated that brine works will soon be established.—*Chemical Trade Journal*.

UNIFORM CUSTOMS IN THE MANURE TRADE.

The committee of the German Agricultural Society, Section for Fertilisers, has, in drawing up the following regulations, performed a work which will greatly assist the trade in fertilising material, and prove of great use to agriculturists.

a.—Packing.

The sacks in which commercial fertilisers are sold must have the following details printed on them in letters of uniform size:—

1. Firm supplying the article.
2. Name of the fertiliser.
3. Amount of useful material contained in the article.

The name of the manufacturer and the composition of the manure must be printed on one side of the sack; the name of the manure may either be on the same side or on

the other side. Sacks containing 50, 75, or 100 kilos. must be used, but the weight need not be recorded on the package.

The following are the *only* names and abbreviations which may be employed for fertilisers: (1) Ammonia-superphosphate, am. sup. (2) Nitrogenous-superphosphate, nt. sup. (*German* st. sup.). (3) Mixture of ammonia-superphosphate and organic nitrogenous matter, am. nt. sup. (4) Saltpetre-superphosphate, salp. sup. (5) Ammonia-saltpetre-superphosphate, am. salp. sup. (6) Ammonia-saltpetre-superphosphate with organic nitrogen, am. salp. nt. sup.

The constituents are always to be named in the following order, and by the following abbreviations: Nitrogen, n. (*German* st.). Phosphoric acid, ph. Potash, k. The amount of phosphoric acid is to be expressed, if necessary, by two numbers, connected by a sign, the first of which always signifies acid soluble in water (*e.g.* Ph. 13 + 2 means 15 per cent. of phosphoric acid, 13 of which are soluble, and 2 insoluble in water).

b.—Details for the various kinds of Fertiliser.

Superphosphate.—When without further qualification only the soluble phosphoric acid need be stated. The nature of the material used in its manufacture does not require to be given. If, however, a portion of the acid is soluble, and the rest insoluble, the amounts of each must be stated.

Precipitate.—Amount of phosphoric acid.

Ground Thomas-slag and Thomas-phosphate meal.—Amount of phosphoric acid and dust.

Bone meal.—In addition to the amounts of phosphoric acid and nitrogen a further statement in agreement with the conditions laid down by the Union of German Research Stations in conjunction with the bone-meal manufacturers, must be made.

Fish guano, flesh meal, Peru guano, fecal guano, poudrette (crude or fine) and **fine bone meal** must be labelled with amount of nitrogen, and total and soluble phosphoric acid.

Ammonia superphosphate prepared from superphosphate and pure ammonium sulphate, must be accompanied by a statement of amount of ammoniacal nitrogen and soluble phosphoric acid.

Nitrogenous and superphosphate mixtures of superphosphates with valuable nitrogenous organic matter (ground leather, wool, &c. being excluded), sometimes alone and sometimes with sulphate of ammonia, simply require a statement of the amount of soluble phosphoric acid and total nitrogen.

Saltpetre superphosphates.—Mixtures of Chili saltpetre with superphosphates require the amounts of nitrogen and soluble phosphoric acid.

Saltpetre ammonia superphosphates, which are similar to the above, but with sulphate of ammonia in addition, require soluble phosphoric acid and total nitrogen to be noted.

Chili saltpetre and ammonium sulphate, delivered in original packing, require no further designation. If, however, they are in any way prepared, they must be labelled as above and with the amount of nitrogen present.

Blood meal, horn meal, and other nitrogenous fertilisers are required to bear their names and the amount of nitrogen present.

Mixtures containing **potash salts** must, in addition to the above, be labelled with the amount of potassium oxide (not salt) present.

c.—Sampling.

The sampling must be done by the purchaser, or his representative at the railway station, or within two days of receipt at the place of delivery, either in the presence of a representative of the seller, or with the assistance of an impartial person, according to the following method.

An average sample must be carefully taken, if possible by means of a sampling iron from the interior of every fifth sack, if the quantity be less than 200 cwt., and of every tenth sack if it exceeds this amount; sacks which have been injured during transport are not to be included. The

samples thus obtained must be well mixed with one another on a clean and dry surface, and three equal samples, each of at least half a pound weight taken out, placed in clean dry glass or earthenware vessels, closed air-tight, sealed, and labelled. A statement must be drawn up by the seller, giving particulars of manufacturer, mark, number of sacks, weight, and guaranteed composition, and must be signed by both parties. In cases of dispute, only such samples as are taken in this way and are accompanied by such a document will be recognised.

These regulations come into force on April 1st, 1891.

It is to be hoped that agriculturists, to whom these regulations give a simple means of control, will do all in their power to assist their introduction, and will make use of the advantages thus offered to them.—*Chemiker Zeitung through Chemical Trade Journal.*

POTASH AND ITS DERIVATIVES.

Review of 1890.

There has been a serious reduction in the production of potash in France during 1890, the chief cause of this being the scarcity of raw material—beetroot salts.

About 24 million kilos. of salts have been refined during the year, and in addition to this the surplus stock of crude potash from the preceding year has been converted into the refined article. In spite of this, several potash refiners have been compelled to stop work, either completely or partially. This lack of raw material is the result of the payment of a bonus to the manufacturer, who is thereby induced to exhaust the molasses to the utmost extent.

The amounts produced have been (about):—

6,000,000 kilos. refined potash, 75—80 and 80—85 per cent.

1,500,000 kilos. extra potash, 88—90 per cent.

1,000,000 kilos. hydrated potashes.

4,000,000 kilos. common salt.

4,500,000 kilos. potassium chloride.

3,000,000 kilos. potassium sulphate.

The potash salts have been chiefly employed for agricultural purposes. The chloride in particular, which is still converted into sulphate by some works in the Nord, is entirely devoted to this purpose, and at a price which would not pay manufacturing industries.

Sulphate of potassium is still partially worked up, but its high price will eventually shut it out, like the chloride, from use in this direction.

The production of potash from suint, which is the source of a regular annual supply, has been much less in 1890 than in the preceding years. Not more than 4 million kilos. of suint potash have been produced in the various French wool-washing establishments, and the deficit of each works may be estimated at nearly a quarter of its total production. It appears that similar conditions will probably exist throughout 1891.

The potash thus produced has been mainly employed in the manufacture of caustic potash, and the remainder sent directly to the soap boilers. The manufacture of caustic potash, of which France appears to enjoy almost a monopoly, and which has been greatly restricted of late years, has developed considerably during 1890. The old works have been fully employed and new ones established, all of which have been able to find a market for their products. More than 2,000,000 kilos. of caustic potash of different qualities have been manufactured, and, for the most part, exported.—*L'Engrais through Chemical Trade Journal.*

SCENTS AND PERFUMES.

In 1889, 44,608 gallons of perfumed spirits, chiefly eau de Cologne, valued at 87,629*l.*, and paying a duty of 10*s.* 6*d.* per gallon, were imported into England. Of essential and perfumed oils there were 1,078,277 *lb.*, valued at 192,340*l.*; and of perfumery and articles used therein, 1,367,847 *lb.*, valued at 139,746*l.* The lavender water distilled at home, the otto of roses, musk, vetiver, Tonquin bean, patchouli, and other perfumes imported, bring up the total to 500,000*l.* sterling. Of orange-flower water, jasmine and neroli oils, citronelle and lemon-grass oils, a great deal are received.

There are about 10,000 acres under *Andropogon nardus* grass in Ceylon, and over 5,500,000 oz. of the citronelle oil made from it are shipped. Lemon-grass oil is obtained from other species, *Andropogon citratus* and *A. schouan-thus*. About 9,000 oz. are shipped from Ceylon. Geranium oil, which is much used to adulterate otto of roses, is distilled in Algeria to the extent of 12,000 lb.

Otto of roses is chiefly produced in Turkey and India. At Kezanlik and its neighbourhood about 80,000 oz. are made. At Adrianople the yield of an average crop of roses is from 600,000 to 825,000 drachms. It requires about 3,000 lb. of rose leaves to produce an ounce of otto of roses. The Turkish oil is that most found in our market; but much of the rose oil which England consumes comes also from India, it being largely distilled in the North-West Provinces and the Punjab. From India there was exported last year 12,128 gallons of different essential oils, valued at 20,277*l*. Of this quantity, 3,000 gallons came to the United Kingdom, 1,000 gallons were sent to France, and nearly all the rest went to the east coast of Africa, Arabia, and Egypt. But if we use a great deal of perfumery, we also export perfumed waters, distillates, and articles of perfumery, to the value of about 110,000*l*. a year.

OLIVE CULTIVATION IN NORTHERN PERSIA.

J. Soc. Arts, 1891, 39, 278—279.

Her Majesty's Secretary of Legation at Tcheran says that this group of villages possesses from 80,000 to 100,000 trees, which yield on an average from 6 to 9 lb. of olives per tree per annum, thus giving an annual produce of 560,000 lb. of olives, if the former average be taken. The quantity of good olive oil derived from the Persian presses may be estimated at 17 per cent. of the olives, which would give 127,000 lb. of good oil. The good oil having been extracted, the residue is again pressed, and an oil of inferior quality is produced, which is used in the manufacture of soap. The value of the oil after a good harvest is 2 *kraus* (about 1*s*. 2*d*.) per bottle of 2 lb. weight, at Resht or Teheran, whereas the maximum price paid per bottle after a bad harvest is 5 *kraus*. In obtaining the oil the following process is employed:—The olives are gathered late in the autumn, and at once stored in a kind of large bin, where they are left to ferment till the first spring suns, that is to say, till about the festival of the Persian new year, March 21. The olives are then spread out to dry on the flat house tops. When perfectly dried, they are again packed till they ferment. After this second fermentation, they are trodden by men, somewhat after the fashion in which grapes are trodden in the wine-press. After having been thus trodden they are boiled, and after boiling crushed in a sort of press between flat stones, a receptacle for the oil being placed beneath the stones. A monopoly for the working and purchase of all the olives in northern Persia was granted to a firm of Russian merchants, in a concession given to them by the Shah in 1890, and in order that no time may be lost in turning a profitable speculation to good account, a member of this firm has, it is said, been already carefully studying the various methods employed in Europe in the pressing and refining of the oil, the method in practice in the olive oil presses of Marseilles having finally been selected by him. Every olive tree in Persia is subject to a government tax of 4 *shahis*, or about 1½*d*. English money.

PAPERS OF INTEREST TO TECHNOLOGISTS AND OTHERS.

Monthly Patent List.

I.—GENERAL PLANT, APPARATUS, AND
MACHINERY.

APPLICATIONS.

2790. L. A. Comolli and C. Conteville. A continual burning gas furnace. Filed February 16. Date applied for October 15, 1890, being date of application in Brazil.

2799. W. T. Lewis. An improved furnace for the better combustion of fuel. February 16.

2946. G. Goodlet. Improvements in apparatus for compressing and accumulating fluids. Complete Specification. February 18.

3051. L. Archbutt and R. M. Deeley. A process for treating chemically softened water so as to prevent the formation of an adherent deposit in the feed apparatus or steam boilers. February 19.

3187. A. W. Ellis. An improved stand for chemical or other purposes. February 21.

3435. E. Nelson. Improvement in method of treating heated liquid wastes, and apparatus therefor. Complete Specification. Filed February 25. Date applied for August 30, 1890, being date of application in United States.

3461. O. Howl. Accessible bends for thick fluids. February 26.

3511. I. Singer and H. A. A. Dombrain. Improvements in apparatus for extraction of liquids from pulverulent materials in which they are absorbed. February 26.

3514. B. Willeox.—From F. Fouche, France. Improvements in apparatus for condensing steam or vapour. February 26.

3668. T. Ledward. Improved apparatus for separating fluids. February 28.

3836. H. E. Newton.—From C. C. Worthington, United States. Improvements in surface condensers. Complete Specification. March 3.

3902. J. F. H. Gronwald and E. H. C. Oehlmann. Improvements in sterilising apparatus. Complete Specification. March 4.

3916. F. Lennard. See Class II.

3952. E. Lowe. Improved apparatus for straining or filtering liquids. March 5.

3955. E. Luck. Improvements in or connected with vacuum distillatory apparatus. March 5.

3997. C. Smith.—From A. de Kunwald, France. Improvements relating to apparatus for pumping, forcing, or exhausting liquids or gases. Complete Specification. March 5.

4065. G. E. Belliss and A. Morecom. Improvements in machinery for compressing atmospheric air and compressing and condensing gases. March 7.

4203. P. Taaffe. An improved apparatus for dealing with the waste products of combustion and other purposes. March 9.

4208. R. J. Hooper-Rastriek. Improvements in apparatus for evaporating solutions, especially suitable for brine. March 9.

4229. R. Hirsch. A process and apparatus for the separation of mixtures of gases. March 9.

4292. The Brins Oxygen Company, Limited, and K. T. Murray. Improvements in apparatus for automatically changing the direction of flow of currents of fluids through pipes or passages. Complete Specification. March 10.

4308. E. B. Caird and T. J. Rayner. An improvement in surface condensers. March 10.

COMPLETE SPECIFICATIONS ACCEPTED.*

1890.

4309. J. Foster. Evaporating and distilling apparatus. March 18.

5038. H. Trott. Apparatus for operating valves for controlling the passage of fluids. March 18.

6088. E. Brook. Improvements in kilns. February 25.

6221. J. W. Lovibond. Instruments for estimating measuring, or comparing colour, texture, and appearance of transparent or opaque bodies, and for testing colour vision and light perceptive power. March 11.

6399. J. von Langer and L. Cooper.—From G. Pietzka. Reverberatory furnaces. March 4.

6484. G. Fletcher. Evaporating pans. March 11.

7075. B. Hunt and W. M. Mackey. Filtering apparatus. March 11.

12,897. G. A. Hart. Kiln for drying moist materials. March 18.

13,127. T. Young. Valves for corrosive and other fluids. March 11.

16,881. J. F. Pease. Improvements in furnaces. February 25.

* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

19,667. C. C. Leathers.—From W. Radam. Tank or vessel for the manufacture of medicines. March 4.

20,318. E. H. Cohn. Sterilising apparatus. March 4.

1891.

84. C. G. Mayer. Refrigerating apparatus. March 4.

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

2889. W. P. Thompson.—From G. S. Sandford, United States. Improvements in apparatus for the manufacture of gas from petroleum oil. Complete Specification. February 17.

2918. J. H. R. Dinsmore. Improvements in or connected with the manufacture of illuminating and heating gases. February 18.

3034. F. Fanta. A new process for producing oxygen gas. Filed February 19. Date applied for, October 22, 1890, being date of application in Belgium.

3042. J. Y. Johnson.—From P. Nadar, France. Improved means or apparatus for producing artificial light for photographic and other purposes. February 19.

3125. P. Dvorkovitz. Improvements in apparatus for making gas and distilling crude hydrocarbon oils. February 20.

3358. P. Dvorkovitz. Improvements in the manufacture of gas from fluid hydrocarbons. February 24.

3367. E. Creighton. Improvements in coal block fuel. February 24.

3475. H. M. Carter and C. E. Fraser. Improvements in the manufacture of brick or briquette fuel. February 26.

3525. J. C. Chandler. Improvements in apparatus for purifying gas. February 26.

3778. A. Gray. Purifying air and gases from mechanically suspended and from gaseous impurities. March 3.

3862. W. Dyson. Improvements in the process of making gas and a product arising therefrom. March 4.

3912. A. Collingbridge. Improved treatment of certain hydrocarbon substances susceptible of general application to illuminating and heating purposes. March 4.

3916. F. Lennard. Improvements in apparatus for carburetting gas or air, or for distilling, evaporating, or concentrating. March 4.

4131. A. B. Lewes. Improvements in or appertaining to the manufacture or production of hydrogen. March 7.

4279. C. F. Claus. Improvements in the purification of water gas or other producer-gas from sulphur compounds. March 10.

4321. J. Baxter and W. Baxter. Improvements in means and apparatus for refining paraffin. March 11.

4500. F. J. Jones. Improvements in gas purifiers. March 13.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

1237. R. Mannesmann. Manufacture of illuminating gas, and apparatus therefor. March 4.

1238. R. Mannesmann. Production of water-gas and illuminating gas, and apparatus therefor. March 4.

1283. O. Imray.—From R. and M. Mannesmann. Production of coke, and apparatus therefor. March 4.

1285. O. Imray.—From R. and M. Mannesmann. Gas producers. March 4.

1236. W. E. Smith.—From S. T. J. Bray. Apparatus for burning liquid fuel. March 18.

4326. C. A. Sahlström and A. F. Hill. Burner for liquid fuel. March 11.

4457. E. Edwards.—From F. Stroeher. Coke ovens, and method of using same. February 25.

5434. H. Williams. Manufacture of water-gas, and other gases for lighting and manufacturing purposes. March 18.

5637. G. C. M. B., and G. A. Fowler. Night-lights and other similar lights. March 4.

5971. J. Dewar and B. Redwood. Distillation of oils and other viscous liquids. March 11.

6217. S. Griffin. Apparatus for producing combustible gas. February 25.

6256. T. D. Rock. Application of anthracite gas to metallurgical and other furnaces. March 11.

6282. R. de Soldenhoff. Means employed in charging coke ovens. March 4.

6466. C. M. Pielsticker. Distillation of hydrocarbon and other oils. March 11.

6575. J. H. W. Stringfellow. Manufacture of gas, and apparatus therefor. March 11.

7335. G. M. Cruikshank.—From J. C. Reissig, P. F. Macallum, and J. Landin. Incandescent lighting, by means of calcareous gas, and apparatus therefor. March 4.

12,638. G. Frank. Compressed fuel. March 18.

16,762. W. P. Thompson.—From A. Mason and J. Wilson. Method and apparatus for burning petroleum and other hydrocarbons. March 18.

17,921. C. Eidle. Machine for charging gas retorts. March 4.

20,002. A. Dauber. Gas producers or generators. March 18.

20,030. L. van Vestrout. Apparatus for charging inclined gas retorts. March 4.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

219. H. E. Ryecroft and A. Mason. Process and apparatus for distilling and refining petroleum and other hydrocarbons; applicable for distilling and refining animal, vegetable, and fruit oils, saccharine juices, syrups, essential oils, &c. March 4.

327. M. Bohm. Distilling crude petroleum, mineral oil, tar, &c., and apparatus therefor. February 25.

1308. C. M. Pielsticker. Continuous distillation of hydrocarbon and other oils and liquids. March 18.

IV.—COLOURING MATTERS AND DYES.

APPLICATIONS.

2805. H. H. Lake.—From Wirth and Co., agents of A. Leonhardt and Co., Germany. Improvements in the manufacture of colouring matters. February 16.

2817. O. Imray.—From the Society of Chemical Industry, Switzerland. Production of orange-yellow to brown azo colouring matters for dyeing and printing. February 16.

2818. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning, Germany. Production of azo colours in discharge printing on indigo dyed fabrics. February 16.

3247. E. Coen. Improvements in the manufacture of copying ink. February 23.

3263. J. C. L. Durand, D. E. Huguenin, and A. J. J. d'Andiran-Koechlin. Manufacture of colouring matters derived from pyrogallie acid, and their application to dyeing and printing. Complete Specification. February 23.

3270. A. Fischesser. An improved process for producing azo colouring matters. February 23.

3439. B. Willeox.—From The Farbenfabriken vormals F. Bayer and Co., Germany. Improvements in the manufacture of azo dyes. February 25.

3622. R. Vidal. Improvements in the production and separation of methylamines, ethylamines, phenylamines, and naphthylamines. February 27.

3758. J. Dawson and R. Hirsch. The manufacture of brown azo colours suitable for dyeing with metallic mordants. March 3.

4543. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik, Germany. The manufacture and production of improved dyestuffs suitable for dyeing vegetable fibre with or without a mordant. March 13.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

4596. S. Pitt.—From L. Cassella and Co. Manufacture of sulphonated thionines. February 25.

4946. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brünig. Production of ethylether of cinnamic acid. February 25.

5722. B. Willeox.—From The Farbenfabriken vormals F. Bayer and Co. Manufacture of diquinoline derivatives. February 25.

5736. O. Imray.—From La Soc. Anon. des Matières Colorantes et Produits Chimiques de St. Denis, A. F. Poirrier and D. A. Rosenstiehl. Manufacture of azo colouring matters derived from azoxyamines. February 25.

6195. S. S. Bromhead.—From Die Chemische Fabrik Grunau, Landshoff, and Meyer. Preparation of new sulphonic acids for the production of a blue colouring matter for cotton. March 11.

6486. J. Imray.—From La Soc. Anon. des Matières Colorantes et Produits Chimiques de St. Denis. Manufacture of nitrated colouring matters. February 25.

6932. C. D. Abel. Manufacture of colouring matters. March 11.

6946. S. Pitt.—From L. Cassella and Co. Production of new basic blue colouring matters. March 11.

7421. R. Holiday. Production and utilisation of a new hydroxyquinone. March 18.

8215. J. Hall. Manufacture of colouring matter. March 18.

8303. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik. Treating alizarine blue for the obtainment of new compounds thereof, and alizarine blue S. February 25.

V.—TEXTILES, COTTON, WOOL, SILK, Etc.

APPLICATIONS.

2753. J. D. Tomlinson and J. Porter. Improvements in means for "gassing" and finishing silk and other yarns and fibres. February 16.

2808. W. Barton. A new or improved process for utilising leather waste, and preparing therewith a material for covering floors, walls, roofs, and the like. Complete Specification. February 16.

3447. T. Mitchell. Improvements in or applicable to the manufacture of linoleum and like floorcloths. Complete Specification. February 25.

3885. E. Dezwarte, and The General Financial and Industrial Corporation, Limited. Improvements in the treatment of ramie, hemp, flax, and other fibrous plants, to obtain the fibres therefrom. March 3.

3960. W. H. Hughes. Cleaning, restoring, and bleaching damaged cotton, or other products from cotton seed, sponges, and all textile material. March 5.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

6155. G. H. Coker. Process and apparatus for removal of fibre or lint from, and cleaning cotton seed. March 4.

14,246. D. Gantillon. Treating silk or mixed fabrics to give them the appearance of China crape. March 11.

18,119. C. Brodbeck. Imparting a silk-like appearance to fabrics, threads, and fibres. March 18.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

2993. J. Leitz and W. Weise. An improved process for printing and shaping textile materials. Complete Specification. February 18.

3385. W. Watson and E. Bentz. A new or improved method of manufacture of certain compounds of chromium used in dyeing and calico printing. February 24.

3931. J. R. Shearer. Improvements in washing, degumming, and bleaching fibrous substances. March 5.

4449. C. S. Bedford. Improvements in the fixation of colouring matters on cotton. March 12.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

1157. G. Young and F. Pearn. Apparatus for dyeing and bleaching cotton and other fibres in the raw, manufactured, and intermediate state. February 25.

6202. S. Stepanow. See Class XI.

7522. W. Elbers. Obtaining designs in red on textile fabrics dyed with indigo. February 25.

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

2812. J. N. Zeitler. Process for converting carbonate of lead, obtained by decomposition of sulphate of lead or other compound of lead with carbonate of sodium, into basic salt. Complete Specification. February 16.

3230. J. Ascough. Improvements in the manufacture of sodium borate of borax, sodium crystal carbonate, or soda and other compounds containing sodium or boron or both. February 23.

3345. J. S. Fairfax.—From F. Crane, United States. Improvements in or relating to sulphuretted solutions and compounds used for the production of films or coatings. February 24.

3557. M. N. d'Andria. Improvements in the manufacture of barium nitrate and strontium nitrate. February 27.

3657. J. J. Howitt. Improvements in or appertaining to apparatus for the manufacture of carbonates of soda. February 28.

3677. B. E. R. Newlands. Improvements in the treatment and utilisation of waste acid liquors from galvanising works. February 28.

3785. J. Simpson. Improvements in the treatment of a certain material (mineral) containing phosphate of lime, for the purpose of obtaining the latter in a highly concentrated condition, as diacidic phosphate, together with certain by-products. March 3.

3925. F. Ellershausen. Improvements in the treatment of soda waste. March 4.

4068. F. M. Lyte. Improvements in the production of chlorine. March 6.

4311. C. F. Claus. Improvements relating to the manufacture of the aluminates, sulphates, and carbonates of soda and potash, and to the production or recovery of alumina and other by-products. March 10.

4429. F. Huter. Improvements in the manufacture or production and utilisation of nitroxyl-chloride. March 12.

4547. J. Anderson and A. Brand. Improvements in the manufacture of carbonates of sodium and potassium and of chlorine. March 13.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

1015. F. Ellershausen. Manufacture of soda and potash. March 18.

3992. G. Horsley and A. C. Wilson. Means or apparatus to be employed in the production of solutions containing sulphurous acid or its salts. March 18.

4174. C. S. Negrier. Method and apparatus for concentrating sulphuric acid. February 25.

4394. F. Ricard. Manufacture of soda by the ammonia process. March 11.

5205. T. Wilton. Saturators used in the manufacture of sulphate of ammonia. February 25.

5442. C. A. Burghardt. Manufacture of nitrate of ammonium and of resulting by-products. February 25.

5574. A. Campbell and W. Boyd. Obtaining chlorine, and utilising calcium chloride or other by-products. March 4.

6116. G. E. Davis and A. R. Davis. Preparation of chlorine. March 11.

6698. G. E. Davis and A. R. Davis. Manufacture of chlorine. March 18.

6834. G. E. Davis and A. R. Davis. Preparation of chlorine. March 11.

13,240. L. M. C. Folie-Desjardins. Process and apparatus for the simultaneous manufacture of phosphorus and of alkali silicates by the treatment of the mineral phosphates of lime, alumina, or bone ash. February 25.

19,121. T. Needham. Packages for putting up chloride of lime, carbonate of ammonia, and other articles and deliquescent substances. March 4.

21,078. J. Leith. Production of bicarbonate of soda and sulphuretted hydrogen, and apparatus therefor. March 4.

VIII.—GLASS, POTTERY, AND EARTHENWARE.

APPLICATIONS.

3365. H. H. Lake.—From E. Sochaczewski, Germany. Improvements relating to the production of a plastic moulding material and to articles made therefrom. Complete Specification. February 24.

3532. C. Breuer. Method of manufacturing artificial stones with glass surfaces. February 26.

4391. T. C. J. Thomas. Improvements in the manufacture of glass. March 11.

4610. F. Plant. Improvements relating to ovens, kilns, or furnaces for firing, pottery, or earthenware, and for other purposes. March 14.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

3286. J. G. Sowerby. Manufacture of glass. March 4.

4592. H. T. Parfitt. Kilns or ovens for firing glass, enamel ware, and for other purposes. February 28.

5830. W. H. Sharnan and R. E. Oldham. Machines for moulding pottery and the like. March 11.

17,255. H. Baggaley. Manufacture of tiles and other porcelain, earthenware, and similar goods. March 11.

17,573. J. Dunnachie. Kilns for firing firebricks, earthenware, and the like. March 18.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

2865. H. F. Williams. An improved composition for paving, roofing, and building purposes. Complete Specification. February 17.

2894. C. Claussen. A new or improved paving. Complete Specification. February 17.

2941. F. G. Edwards. Improvements in the combination of iron and concrete, or similar materials for building purposes. February 18.

3035. B. H. Thwaite. Improved methods of manufacturing Portland cement, and in apparatus therefor. February 19.

3086. H. Parry. Improvements in kilns for burning lime. February 20.

3351. R. R. Coursen. Improvements in plaster slabs. Complete Specification. February 24.

3532. C. Breuer. See Class VIII.

3581. J. W. Savage. An improved road paving. February 27.

3797. G. H. Skelsey. Improvements in the manufacture of Portland cement. March 3.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

5581. G. H. Skelsey. Cement and other kilns. March 4.

5749. W. R. Taylor. Method and means for manufacturing cement. February 25.

20,164. T. Curran. Portable plaster slabs, methods of making same, and moulds therefor. March 11.

X.—METALLURGY, MINING, Etc.

APPLICATIONS.

2747. W. Hutchinson and F. W. Harboard. The utilisation of blast furnace and other slags in conjunction with finely divided oxides of iron. February 16.

3001. J. Gardner. Improvements in the utilisation of, or the manufacture of useful products from "lead bottoms," or other sulphates of lead. February 19.

3057. C. A. Faure. Improvements in the manufacture or production of aluminium alloys. Filed February 19. Date applied for December 2, 1890, being date of application in United States.

3222. J. Clark and G. W. Clark. Improvements in reducing metallic oxides. February 23.

3226. S. R. Smyth, of the Steel and Iron Co., Lim. Improvements in the treatment and smelting of ores and metals in furnaces, and in the apparatus connected therewith. February 23.

3278. A. French and W. Stewart. Improvements in obtaining gold, silver, and copper from ores. February 24.

3348. B. C. Tilghman and R. A. Tilghman. The manufacture of chilled iron globules. Complete Specification. February 24.

3387. H. Lafone. Improvements in and connected with the manufacture of aluminium from alumina. February 25.

3510. J. Lang and F. H. Wigham. A process for protecting iron and steel wire against corrosion. February 26.

3624. R. Millar. Improvements in the casting of metals to secure solidity and homogeneity. February 28.

3992. C. T. J. Vautin. An improved hydro-metallurgical method of the extraction of gold or platinum from their ores. March 5.

4050. M. Mannesmann. Improved method of and apparatus for forming rolling, and calibrating metals. March 6.

4069. T. Casner, C. H. Fitzmaurice, and T. H. Dale. Improved metallic compound. March 6.

4146. R. B. Hansell. Improvements in the castings of ingots for the manufacture of weldless tires, bars, and such like. March 7.

4384. J. von Ehrenwerth. Improvements in processes and appliances for the manufacture of iron and steel. March 11.

4396. J. Strap. Process for the separation of copper, nickel, and silver from matts or alloys containing the same, and the treatment of the residues resulting therefrom. March 11.

4549. W. E. May. Improvements relating to the casting and working of metals, and to apparatus for use in connexion therewith, and for other purposes. March 14.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

840. R. Mannesmann. Means for mixing molten metal in furnaces or converters. February 25.

4560. T. Teague. Refining raw tin, and extracting and utilising the combined metals therefrom. February 25.

5545. A. Turner, A. Baird, and M. B. Baird. Manufacture of iron and steel. March 18.

5937. W. C. Loe. Treating metal-bearing bodies, and recovery of metals therefrom. March 11.

6256. T. D. Rock. See Class II.

6316. S. Fox. Manufacturing steel in connexion with the open-hearth system. March 4.

6821. Sir H. H. Vivian, Bart. Manufacture of copper. March 18.

6960. J. Neill. Manufacture of steel-plated and gated ingots, and moulds for same. March 18.

7129. J. D. Danton. Process and apparatus for reduction of iron and other oxide ores, and for fusion and purification of the produced metals. March 18.

13,723. F. H. Molesworth. Treating metalliferous ores. March 18.

15,341. O. B. Peck. Treatment of slag, and removal thereof from furnaces. March 18.

15,342. O. B. Peck. Apparatus for treatment of slag. March 18.

15,343. O. B. Peck. Centrifugal apparatus for treating molten material. March 18.

15,348. O. B. Peck. Centrifugal apparatus for treating molten material. March 18.

15,349. O. B. Peck. Centrifugal apparatus for treating molten material, and means for removing the said material from such apparatus. March 18.

18,726. M. R. Garcia. Recovery of tin from tin plate and other sources. March 11.

19,164. J. Johnson. Reduction of iron ores. March 18.

21,129. H. C. W. Harmsen. Untinning the waste of tin plates by heating it with fused nitrate of potash or soda. March 18.

1891.

652. O. B. Peck. Machinery for centrifugally treating particles of metallic or mineral-bearing substances of different specific gravity. March 11.

674. O. B. Peck. Machinery for centrifugally treating particles of metallic or mineral-bearing substances of different specific gravity. March 11.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

APPLICATIONS.

19,942A. W. P. Thompson.—From F. Marx, Germany. Improvements in the electro-chemical formation of chlorine and chlorine compounds. Complete Specification. March 5. Originally included in No. 19,942 of December 6, 1890, and therefore takes that date.

2798. H. J. Altman. Improvements in solutions and salts for electro deposition and other purposes. February 16.

2876. E. R. Dale. Improvements in the application of electricity to various useful purposes. February 17.

3003. E. W. Mayer. Improvement in element for electric battery. February 19.

3170. D. Rylands. Improvements in the manufacture of Leclanché cells. February 21.

3198. F. Poudroux. Improvements in galvanic batteries. February 21.

3331. S. C. C. Currie. Improvements in secondary or storage batteries. Complete Specification. February 24.

3336. H. H. Lake.—From H. Lemp and L. M. Schmidt, United States. Improvements relating to welding, brazing, or otherwise joining metal strips, bars, rods, and the like by electricity, and to apparatus therefor. Complete Specification. February 24.

3349. M. W. Dewey. Improvements in electric welding apparatus. Complete Specification. February 24.

3417. W. H. Munns.—From G. A. Smith, Canada. An improved galvanic battery. February 25.

3450. W. H. Power. Improvements in primary batteries. February 25.

3524. R. D. Sanders. Improvements in apparatus for use in the manufacture of metal tubes by electro-deposition. February 26.

3589. H. H. Lake.—From W. B. H. Dowse, United States. Improvements in electric batteries. Complete Specification. February 27.

3738. J. Marx. Improvements in and apparatus for electrolysis and bleaching. March 2.

3789. B. J. B. Mills.—From A. Bellemain, France. Improvements in the depolarisation of electric batteries. March 3.

3799. A. Clark. A new or improved solution or composition for charging electric batteries. March 3.

4044. R. H. Simpson. Improvements in electrical storage batteries or accumulators. March 6.

4188. J. A. Mays. Improvements in electrolysis. March 9.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

5938. K. E. Boettcher. A new secondary element. March 4.

6202. S. Stepanow. Electrolytic preparation of a liquid for bleaching fabrics, paper pulp, &c. March 18.

6223. M. Ancizar.—From R. Z. Bayon. Galvanic batteries. March 18.

9861. A. J. Boulton.—From D. Tommasi and C. Therye. Electrical storage batteries. March 11.

20,126. C. E. Dutton, jun. Galvanic batteries. February 25.

20,510. W. P. Thompson.—From C. L. Coffin. Welding and otherwise working metals electrically. February 25.

1891.

400. T. D. Bottom. The desilverisation of lead, and simultaneous manufacture of white lead by electrolysis of argentiferous lead. March 11.

667. W. P. Thompson.—From The Hess Electric Storage Battery Co. Electrodes for voltaic accumulators. February 25.

XII.—FATS, OILS, AND SOAP MANUFACTURE.

APPLICATIONS.

2998. W. P. Thompson.—From A. H. J. Bergé, E. A. Stein, and E. J. A. de Roubaix, Belgium. Improvements in the saponification of fatty substances by the action of sulphurous acid or bisulphites under pressure. February 19.

3584. E. Livesey and J. Warburton. An improved lubricating composition. February 27.

3768. W. F. Butler. Improved apparatus or means for liquefying or heating grease, oils, or the like. March 3.

4446. W. S. Chenhall and W. F. S. Chenhall. An improved method for the solidification of mineral, animal, and vegetable oils, and volatile and inflammable fluids. March 12.

4454. R. Stone. Improvements in the manufacture of soap, and in the utilisation of the residue of the substances used therein. March 12.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

3503. M. Williams. A new or improved soft soap, and manufacture of same. March 11.

7019. C. A. Serre. Manufacture of soap. March 11.

21,196. J. W. Evans. Improvements in the naphtha process of extracting oil. February 25.

XIII.—PAINTS, PIGMENTS, VARNISHES, AND RESINS.

APPLICATIONS.

3573. T. Holden. An improved antifouling preparation or compound for the preservation of bright or polished metallic surfaces. February 27.

3832. J. H. Noad. A process for manufacture of white lead. March 3.

3887. G. H. Hedley. Improvements in the manufacture of red oxide of iron. March 4.

4334. W. Grimshaw. Improvements in the preparation of pigments or colouring compounds. March 11.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

5380. A. F. St. George. Method and apparatus for preparing copal and other gum resins and resins, and for manufacturing varnish. March 18.

16,786. W. A. Hall. Manufacture of paints. March 4.

17,346. J. Hoake. Preparation of colours for distemping. March 11.

19,160. M. E. Dejonge. Anti-corrosive and anti-fouling compounds. March 18.

20,690. A. van Winkle and E. N. Todd. Protecting sheets of gelatin by pyroxiline or nitro-cellulose varnishes. March 11.

XIV.—TANNING, LEATHER, GLUE, AND SIZE.

APPLICATIONS.

2808. W. Barton. See Class V.

3176. W. Bolt. A quicker process for tanning all kinds of hides or skins. February 21.

3910. O. Brunner. Improvements in and relating to the waterproofing of leather. March 4.

4234. H. A. Harvey. Improved compositions for treating, colouring, and dressing leather. March 10.

4385. A. Foelsing. Process for clarifying and bleaching tannin extracts or tannin liquors. March 11.

4586. W. A. Brown. An improved light size or cop-bottom paste for cotton spinners and manufacturers. March 14.

COMPLETE SPECIFICATION ACCEPTED.

1890.

7509. F. R. Maggs. The preparation of skins, kips, and hides by an improvement in the process known as "un-hairing" or pulling. February 25.

XVI.—SUGARS, STARCHES, GUMS, Etc.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

7737. A. Niemöller. Production of glutinous material from the seed kernels of the fruit of the carob tree (*Ceratonia*). March 11.

8029. E. Steiger, E. Schulze, and C. Auer-Schollenberger. Treating vegetable cellular membranes to obtain glutinous substances. March 11.

XVII.—BREWING, WINES, SPIRITS, Etc.

APPLICATIONS.

2936. H. J. Haddan.—From J. Batallé, Spain. A method of improving wine and other alcoholic liquors. Complete Specification. February 18.

3207. G. F. Redfern.—From J. Hradil, Germany. An improved method of increasing the formation of cells during the process of fermentation. February 21.

3978. F. L. Calhant. The manufacture of charcoal from sawdust, wood shavings, and the like, and the treatment of wine, alcohol, brandy, cider, beer, and other matters therewith. March 5.

4153. J. Laing. Improvements in the distillation of alcohol, and in apparatus therefor. March 9.

4196. F. T. Simson and J. Cox. Improvements in malt liquors, fermented wines and spirits. March 9.

4207. G. A. Clowes. Improvements in fermentation. March 9.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

5673. J. Safamon. Fermenting process for beer, wine, &c. February 25.

13,694. M. König. Malt curing apparatus. March 11.

18,212. E. J. Mills and R. Barr. Treatment of alcoholic liquids. January 28.

20,430. P. L. F. E. Vignier. Improvements in the manufacture of pure grape spirit, in apparatus used for same or other spirits, and in the ageing of the same. March 4.

20,985. H. H. Lake.—From H. Götter. Manufacture of fermented liquids, and apparatus therefor. February 25.

1891.

1214. A. G. Barkhardt and G. Schule. Apparatus for distilling and rectifying. March 18.

XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, AND DISINFECTANTS.

APPLICATIONS.

A.—Chemistry of Foods.

2816. O. Imray.—From Calberla, Fitz, and Consorten, Germany. Process and apparatus for sterilising liquids. February 16.

2944. J. Oakhill and R. H. Leaker. An improved process for preserving milk. February 18.

3257. H. M. Dowson. Improvements in the use and application of malt culms for food purposes. February 23.

3481. J. Hillaby. A preparation of extract of malt in combination with extract of liquorice and other substances. February 26.

3842. J. Stube and M. Spiro. A process for increasing the value of whey. March 3.

4195. F. T. Simson and J. Cox. Improvements in food preparations and medicines. March 9.

4288. J. White. Improvements in or connected with the manufacture of table jelly. March 10.

4291. W. Robertson. An improved article of food or solidified malt extract jelly. Complete Specification. March 10.

B.—Sanitary Chemistry.

2846. A. McDougall and J. J. Meldrum. Improvements in the disinfection and deodorisation of sewage, and in the apparatus for preparing and applying the disinfectant. February 17.

4177. W. H. Watson. Improvements in the means employed for the purification and discolouration of water, dye, and other manufacturing refuse liquors, sewage, or other aqueous or saline liquids. March 9.

4243. C. W. Chancellor. A method of and apparatus for the treatment and disposal of sewage. March 10.

4284. R. H. Twigg. Improved means and apparatus for effecting oxidation of organic matters contained in liquids. March 10.

4390. E. Devonshire. Improvements in apparatus for purifying or treating water. March 11.

C.—Disinfectants.

3242. F. Idle and I. Pearson. A fire lighter and disinfectant. Complete Specification. February 23.

4352. A. Lutschannig. A new or improved manufacture, being a disinfectant, antiseptic, deodoriser, vermin and insect destroyer, and also applicable for use in an ingredient in and as fire lighters. March 11.

COMPLETE SPECIFICATIONS ACCEPTED.

B.—Sanitary Chemistry.

1890.

6252. J. Longshaw. Apparatus for filtering or purifying water, sewage, &c. March 11.

XIX.—PAPER, PASTEBOARD, ETC.

APPLICATIONS.

2872. J. Beveridge. Improvements in the treatment of fibrous plants for the manufacture of paper pulp. February 17.

3061. J. Feirabend. A process for the manufacture of cellulose wadding. February 19.

3878. R. N. Redmayne. An improvement in the manufacture of paper pulp for paper-making and other purposes. March 4.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

4360. J. Robertson. Glazing paper, and apparatus herefor. March 18.

6993. C. Kellner. Apparatus for separating or disintegrating fibres in the manufacture of paper pulp. February 25.

17,268. A. Wilbaux. Treatment of vegetable parchment and the like. February 25.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

APPLICATIONS.

3731. W. Noetzel, M. Rapp, and E. Istel. Process for the manufacture of symmetrical diamido-diphenyl-thio-urea. March 2.

4487. R. Ancizar.—From Rafael Zerda-Bayon, Colombia. Improvements in the manufacture of sulphate of quinine. March 12.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

249. H. E. Rycroft and A. Mason. See Class III.

853. A. J. Boulton.—From O. Schweissinger and L. Hoffmann. Manufacture of extract of hops. February 25.

XXI.—PHOTOGRAPHIC PROCESSES AND MATERIALS.

APPLICATIONS.

2880. T. R. Dallmeyer. Improved means and devices for obtaining optical projections of photographs in natural colours. February 17.

2956. W. G. Thomson and W. Ward. Improvements in the method of and apparatus for focussing in photography. February 18.

3219. S. Waters. Improvements in the art of photographing in colours, and in the means employed therein. February 21.

4049. S. H. Crocker. Improved means for producing photographs in colours. March 6.

4062. W. P. Thompson. Improvements in photography. March 6.

XXII.—EXPLOSIVES, MATCHES, Etc.

APPLICATIONS.

2970. W. P. Thompson.—From La Société Coignet and Cie., France. Improvements in the manufacture of phosphorus in sticks or blocks. Complete Specification. February 18.

3184. J. T. Mackintosh. Improvements in wax and wooden matches. February 21.

3208. H. Maxim. Improvements relating to the manufacture of nitro-substitution compounds of cellulose. February 21.

3679. G. A. Rosenkolter. Improved lucifer matches. Complete Specification. February 28.

3881. G. A. Rosenkolter. Improvements in the manufacture of lucifer matches. Complete Specification. March 4.

4129. H. Maxim. Improvements relating to the manufacture of nitro-substitution compounds of cellulose. March 7.

4184. F. Wilson. An improved method of treating picric acid as an explosive. March 9.

4381. E. A. Ventris. To secure a greater certainty in the burning of any matches when lighted. March 11.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

3819. E. C. Mance. Signal rockets. March 4.

5209. H. H. Lake.—From H. S. Maxim. Manufacture of explosives, and apparatus therefor. February 25.

5535. R. Low. Percussion fuses. February 25.

7301. C. O. Lundholm and G. H. Hosié. Manufacture of explosives. March 18.

1891.

330. C. R. E. Bell. Manufacture of matches. March 18.

XXIII.—ANALYTICAL CHEMISTRY.

APPLICATION.

2785. A. Tropéas and A. E. Weels. Improvements in apparatus and appliances for the rapid determination of carbon of steel. February 16.

THE JOURNAL OF THE Society of Chemical Industry:

A MONTHLY RECORD

FOR ALL INTERESTED IN CHEMICAL MANUFACTURES.

No. 4.—Vol. X.]

APRIL 30, 1891.

[Non-Members 20/- per annum; Members 21/- per Set of extra or back numbers: Single Copies (Members only) 2/6.]

The Society of Chemical Industry.

Past Presidents:

Sir H. E. Roscoe, M.P., LL.D., V.P.R.S.	1881—1882.
Sir Frederick Abel, C.B., D.C.L., F.R.S.	1882—1883.
Walter Weldon, F.R.S.	1883—1884.
W. H. Perkin, Ph.D., F.R.S.	1884—1885.
E. K. Muspratt	1885—1886.
David Howard	1886—1887.
Prof. James Dewar, F.R.S.	1887—1888.
Ludwig Mond	1888—1889.
Sir Lowthian Bell, Bart., F.R.S.	1889—1890.

COUNCIL FOR YEAR ENDING JULY, 1891.

President: E. Rider Cook.

Vice-Presidents:

Sir Lowthian Bell, Bart., F.R.S.	Ludwig Mond.
R. Forbes Carpenter.	Dr. Hugo Muller, F.R.S.
Prof. James Dewar, F.R.S.	B. E. R. Newlands.
James Duncan.	Dr. W. H. Perkin, F.R.S.
David Howard.	Dr. Edw. Schunck, F.R.S.
S. H. Johnson.	J. C. Stevenson, M.P.

Ordinary Members of Council:

A. H. Allen.	Prof. R. Meldola, F.R.S.
L. Archbutt.	F. K. Muspratt.
S. B. Boulton.	T. L. Patterson.
Jno. Brock.	Jno. Pattinson.
Jno. Calderwood.	Jno. Spiller.
H. Grimsshaw.	T. W. Stuart.

With the Chairmen and Secretaries of Sections.

Honorary Treasurer:

E. Rider Cook, East London Soapworks, Bow, E.

Honorary Foreign Secretary:

Dr. F. Hurter.

General Secretary: Charles G. Cresswell.

Offices:

Palace Chambers, 9, Bridge Street, Westminster, S.W.

THE JOURNAL.

Publication Committee:

The President.

Sir F. A. Abel, F.R.S.	Prof. A. K. Huntington.
A. H. Allen.	F. Hurter, Ph.D.
L. Archbutt.	Ivan Levinstein.
G. H. Bailey, D.Sc., Ph.D.	Prof. R. Meldola, F.R.S.
Joseph Bernays, M.I.C.E.	Ludwig Mond.
H. Brunner.	E. K. Muspratt.
Prof. Frank Clowes, D.Sc.	B. E. R. Newlands.
W. Y. Dent.	C. O'Sullivan, F.R.S.
Prof. Jas. Dewar, F.R.S.	John Pattinson.
John Heron.	W. H. Perkin, Ph.D., F.R.S.
D. B. Hewitt, M.D.	Sir H. E. Roscoe, M.P., F.R.S.
David Howard.	John Spiller.
Prof. J. J. Himmell.	A. Norman Tate.
	Thomas Tyrer.

Editor:

Watson Smith, University College, London, W.C.

Assisted by the following Staff of Abstractors:

S. B. Asher Aron. IV., IX., X.	J. Walter Leather, } XV.
H. Amer. VII.	Ph.D. }
T. L. Bailey, Ph.D. Gen. Chem.	F. H. Leeds. III., XXI.
G. H. Beckett. V., VI., VII.	A. Liebmam, Ph.D. } IV., VI.,
D. Bendix. III.	XX.
E. Bentz. IV., V., VI.	A. R. Ling. IV., XVI.
Jos. Bernays, M.I.C.E. I.	D. A. Louis. XV.

NOTICES.

In accordance with the provisions of Rule 18 of the Bye-laws, notice is hereby given that those Members of Council whose names are placed in italics in the annexed list will retire from their respective offices at the forthcoming Annual General Meeting.

Professor J. Emerson Reynolds, F.R.S., has been nominated to the office of President; and Mr. E. Rider Cook has been nominated Vice-President under Rule 11.

Dr. John Evans, F.R.S., Mr. A. Norman Tate, and Sir John Turney, have been nominated Vice-Presidents under Rule 8.

The Treasurer and Foreign Secretary have been nominated for re-election.

Members are hereby invited to nominate fit and proper persons to fill four vacancies among the Ordinary Members of Council under Rule 18. Special nomination forms for this purpose can be obtained from the General Secretary upon application.

Extract from Rule 18.—"No such nomination shall be valid unless it be signed by at least ten Members of the Society who are not in arrear with their subscriptions, nor unless it be received by the General Secretary, at the Society's Office, at least one month before the date of the commencement of the Annual General Meeting, to the election to take place at which it refers. Nor shall any such nomination be valid if the person nominated be ineligible for election under Rules 12 or 13. No member shall sign more than one nomination form."

ANNUAL GENERAL MEETING.

Notice is hereby given that the next Annual General Meeting will be held in Dublin on Wednesday, Thursday, and Friday, the 8th, 9th, and 10th of July next. Detailed arrangements and the programme of proceedings will appear as soon as complete. Tickets of membership will be issued in time for the meeting, and will form, as heretofore, vouchers for visits to works and excursions.

Post Office Orders should be made payable at the General Post Office, London, to the Honorary Treasurer, E. Rider Cook, and should be forwarded to him at Bow, unless it be desired to notify a change of address.

Members who require extra sets or back numbers of the Journal are requested to make application to the General Secretary only, to whom also changes of address should be communicated.

Authors of communications read before the Society, or any of its Local Sections, are requested to take notice that under Rule 41 of the bye-laws, the Society has the right of priority of publication for three months of all such papers. Infringement of this bye-law renders papers liable to be rejected by the Publication Committee, or ordered to be abstracted for the Journal, in which case no reprints can be furnished to the author.

Notice is hereby given, for the information of members and advertisers, that the advertisement columns of this Journal have been contracted for by Messrs. EYRE and SCOTTISWOOD, the Society's printers and publishers, to whom all communications respecting them should be addressed.

The Secretary is instructed to negotiate for the purchase of copies of the Society's Journal for January and May 1883, and January, February, and April 1886. Members possessing odd copies of these numbers are particularly requested to communicate at once, stating price required, with Mr. Cresswell. The stock of all other numbers is at present sufficient for the Council's requirements.

LIST OF MEMBERS ELECTED. 23rd APRIL, 1891.

- Blass, Edw., Essen (Ruhr), Germany, civil engineer.
 Boyd, Saml. F., 18, Leeson Park, Dublin, manufacturing chemist.
 Brewis, Edw. Theodore, c/o Boileau and Boyd, Bride Street, Dublin, works chemist.
 Burnet, Henry K., North Brook Vitriol Works, Bradford, Yorks, vitriol maker.
 Conradson, Pontus H., Great Northern Railroad, St. Paul, Minn., U.S.A., chemist.
 Cotton, Chas. P., Ryecroft, Bray, co. Dublin, engineer-in-chief, Local Government Board.
 Cotton, Wm. F., Hollywood Roebuck, co. Dublin, secretary and manager, Gas Company.
 Geoghegan, Saml., St. James's Gate Brewery, Dublin, mechanical engineer.
 Gorvin, Jno. C., English Crown Spelter Works, Port Tennant, Swansea, assayer.
 Heaton, Jno., Chemical Works, Wicklow, Ireland, manager.
 Hetherington, Albert E., 32, High Street, Wavertree, Liverpool, chemical student.
 Holliday, Jno., St. James's Gate Brewery, Dublin, mechanical engineer.
 Hopkinson, Jno., Marion Street, Lister Hills, Bradford, Yorks, viscosine lubricant manufacturer.
 James, J. Herniman, Welwyn Lodge, Swansea, assayer.
 Macallan, John, 171, St. Helen's Terrace, Clonliffe Road, Dublin, analytical chemist.
 Mackenzie, Jas. Scott, 132, Tritonville Road, Sandymount, Dublin, shipowner.
 Phillips, G. Brinton, 2007, De Lancey Place, Philadelphia, Pa., U.S.A.
 Pigot, Thos. F., Royal College of Science, Stephen's Green, Dublin, professor of engineering.
 Ross, Wm., 66, North Wall, Dublin, mechanical engineer.
 Ryder, Arthur Gore, First Lock, Grand Canal, Dublin, cement manufacturer.
 Taylor, Malcolm, 18, Forest Road, Cloughton, Birkenhead, chemical student.
 Thomson, A. W. Ferguson, 14, Hills Place, Oxford Circus, W., iron merchant.
 Tiebhorne, Dr. Chas. R. C., 15, North Great George Street, Dublin, professor of chemistry.
 Valentine, Geo., St. James's Gate Brewery, Dublin, analytical chemist.
 Wells, Jas. G., 26A, St. Paul's Street West, Burton-on-Trent, brewery chemist.
 Wilson, Wm. Wesley, St. James's Gate Brewery, Dublin, civil engineer.

CHANGES OF ADDRESS.

- Aldrick, E. J., 10 Charles Street; 26, Alpha Road, West Ferry Road, Millwall, E.
 Bott, Dr. Wm., 10 Baffles Institute; Government Science Lecturer, Singapore, S.S.
 Burn-Murdoch, J. V., 10 Transvaal; Riverhead Vicarage, Sevenoaks, Kent.
 Callander, W. S., Journals to Phoenix Alkali Works, Widnes.

Conrad, E. C., 1/o Gravesend; Strooofabriek, Raamsdonk, Holland.

Fielding, Patrick J., 1/o Blackrock Road; 8, St. Joseph's Place, Cork, Ireland.

Haig-Brown, R., 1/o Old Trafford; 21, Ladyborn Road, Fallowfield, Manchester.

Hasenclever, R., Chemische Fabrik Rhenania, Aachen (not "Anahe") Prussia.

Heywood, J. H., 1/o 68; 127, Sutherland Avenue, Maida Vale, W.

Isherwood, Oswald, 1/o Crescent View; 105, West High Street, Salford.

Lomas, Thos., 1/o Weston; Cleveland, Minchhead, Taunton, R.S.O.

Maconochie, J. R., 1/o East India Avenue; Saracen's Head Buildings, Snow Hill, E.C.

Mellon, E. L., 1/o Clayton Bridge; Malvern Grove, Withington, Manchester.

Merry, Jas. S., 1/o Richmond Villas; 1, Somerset Place, Swansea.

Morris, Herbert N., Liffordale, Manley Road (not Manby Road), Manchester.

Muir, J. Stanley, Journals to 27, Huntley Gardens, Kelvinside, Glasgow.

Pitblado, L., Journals to Mount Albion, via Bertherton, Queensland.

Procter, H. R., 1/o Tynemouth; Yorkshire College, Leeds; and (Journals) 4, Montpellier Terrace, Hyde Park, Leeds.

Sadler, A. E., 1/o Sandside; Sand Hall, Ulverston.

Sill, T. T., 1/o Walsend; Runcorn Soap and Alkali Co., Lim., Weston, near Runcorn.

Smith, J. Tertius, Pattiswick Hall, Braintree; and (Journals) c/o Jeyes Sanitary Compounds Company, Limited, Plaistow, E.

Speakman, Jas., 1/o Dundee; Cree Hill P.O., Calgary, Alberta, Canada.

Terry, Albert, 1/o Kew; Verulam, Mont Albert Road, Balwyn, near Melbourne, Victoria.

Thorne, Dr. L. T., 1/o Tooting; 8, Dynevor Road, Richmond-on-Thames.

Vanderbergh, Dr. F. P., 1/o The University; 32—33, Lewis Block, Buffalo, N.Y., U.S.A.

Wallace, Robt., 1/o Belfast; 1, Coates Place, Edinburgh.

Welsh, T. L., 1/o St. Vincent Crescent; 3, Prince's Gardens, Dowanhill, Glasgow.

Wood, Milton R., 1/o Brooklyn; Wyandotte, Mich., U.S.A.

Yule, Wm., 1/o Sunderland; Hollins Paper Works, Darwen, Lancashire.

Zinkeisen, Wm., 1/o Berlin; 508, New City Road, Glasgow.

London Section.

Hon. Local Sec. and Treasurer:

T. W. B. Mumford, 1, Glendale Villas, Sydenham Road, Wanstead, E.

The names in italics are those of members of Committee who retire at the end of the current Session.

The following have been elected to fill the vacancies, and will take office in July next:—*Committee:* C. F. Cross, J. Heron, W. Kellner, G. N. Stoker, and F. Namer Sutton.

SESSION 1890—91.

May 14th.—Mr. L. Arrhenius and Mr. R. M. Peasey, "An Improved Process for Softening and Clarifying Water."

June 1st.—Dr. W. S. Squire, "The Artificial Production of Cold theoretically and practically explained."

Meeting held Monday, March 16th, 1891.

MR. THOS. TYRER IN THE CHAIR.

OBSERVATIONS MADE IN THE WORKING OF VITRIOL CHAMBERS.

BY WILLIAM CROWDER, F.I.C.

IN an article in a recent number of the "Nineteenth Century," Sir Benjamin Baker commenced as follows:—"Writing 40 years ago on the future of science, Monsieur Ernest Renan said the work of the 19th century should be the writing of monographs on every point of science, a hard, humble, and laborious task no doubt, but a solid and lasting work withal, as for many long years science will stand in need of those patient researches that might take the title of 'Memoranda for the use of Somebody.'"

It is in this spirit that I desire to lay before you the results of a long series of observations on certain special points in the manufacture of sulphuric acid in the hope that the results may, in the words of Monsieur Renan, prove to be memoranda for the "use of somebody."

It is with extreme diffidence that I approach the subject on which I propose to address you this evening, and I will at once say that my object is not to discuss the theory of the process of vitriol making, but simply to record a series of observations upon a large plant that has been under my own superintendence for many years, and upon which I have bestowed a great deal of time and attention in order to obtain results that would enable me to gain a clear insight into the consecutive changes that take place from the burning pyrites at the kilns to the finished product from the chambers.

The process of vitriol making is so well known that it is unnecessary for me to enter into any detailed description. Nevertheless we are sometimes apt to assume a greater familiarity on the part of our audience with details which can only be familiar to those who are in daily contact with the operations.

Drath.

Alex. Whitelaw, 87, Sydney Street, Glasgow. March 13th.

I propose therefore to give you (first) a short *résumé* of the process. Next, a description of the plant of a well-equipped vitriol works. Then the function performed by each portion of the plant and the means of control, and finally, a consideration of the working of the plant as a whole.

Under one or other of these heads I shall introduce the results of my own observations.

The process of vitriol making consists in the production of sulphurous acid, by burning pyrites or bisulphide of iron (which contains about half its weight of sulphur) in suitable furnaces and conveying the gas so formed into large leaden chambers along with a certain proportion of air, a proportion of nitric acid vapours, and a proportion of water in the form of steam. These various gases and vapours react upon each other, cause, first, a reduction of the nitric acid to the second oxide of nitrogen, and this, on coming in contact with the oxygen of the air, becomes re-oxidised, again becomes reduced by fresh portions of sulphurous acid, and thus the circle of operations is completed, so that, except for losses which occur from various causes, the process is continuous as long as any sulphurous acid remains.

The plant of a complete acid works consists of:—

- Kilns for burning the pyrites.
- An arrangement for producing nitric acid.
- The nitre stack and flue leading to the Glover tower.
- The Glover tower or denitrator.
- The cooler and storing tanks.
- A series of leaden chambers.
- The Gay-Lussac or absorbing tower.
- The exit from the tower and its pipe and damper leading to the chimney for the discharge of the waste gases.
- The air engine and compressors and eggs for raising acid to the towers.
- Boilers for raising steam.

It is observations I have made in working these different portions of the plant which forms the subject of my paper this evening.

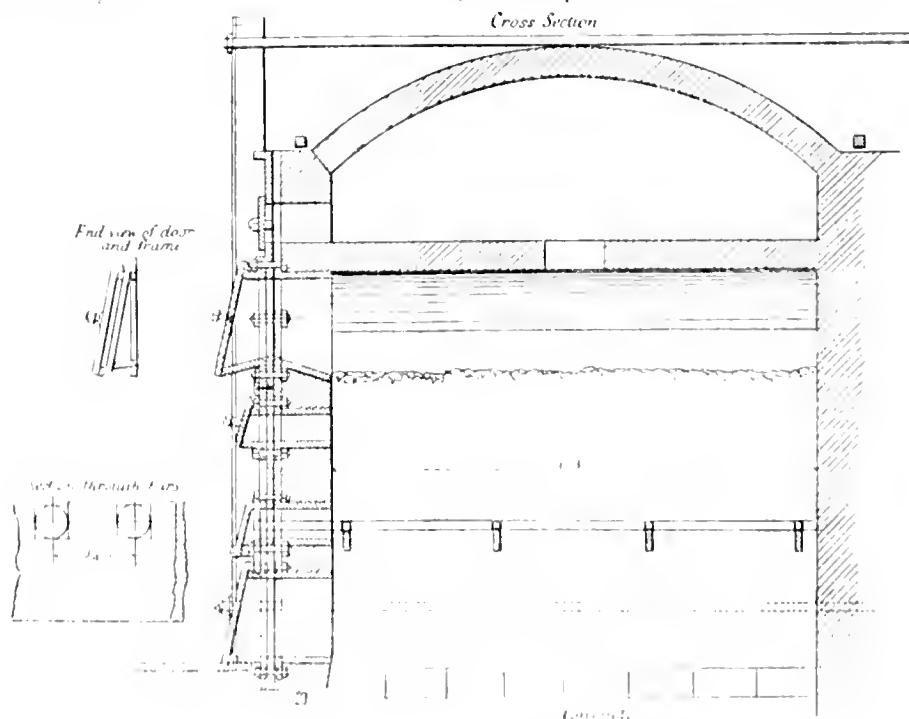

The essential portions of a sulphuric acid works are the kilns, nitre pots and stack, and the chambers; the towers and coolers are of comparatively recent introduction, and although indispensable in the economic production of the acid, have really nothing to do with the original process, there being many works where towers are not employed even to this day.

The diagrams on the wall show sketches of these various portions of the plant. I propose to discuss them separately and to describe some of the results of working them.

The first diagram (see p. 302) is merely a sketch, not drawn to scale, to show the sequence of the operations, beginning with the kilns and showing the course of the sulphurous gas and air as it passes through the nitre oven into the pipe leading to the Glover tower, passing out of the tower into the first chamber and traversing each chamber successively, arriving finally at the exit pipe leading to the absorbing tower, and conveying the waste gases from thence to the chimney.

Kilns.—For the production of sulphurous acid the pyrites is burned in suitable kilns which are chosen according to the kind of ore to be treated. These kilns are of two kinds, viz., those for burning lump ore and those for burning the smalls, *i.e.*, the portion of dust which is either produced in breaking the ore to a uniform size or the small ore which is obtained in the process of mining in Spain.

The kilns for lump ore are very simple in construction, being merely a series of square fireplaces arched over, and their products of combustion led into a common flue to the Glover tower. But the kilns for burning smalls are much more complicated and difficult to manage.

SECTION OF LUMP ORE KILNS.

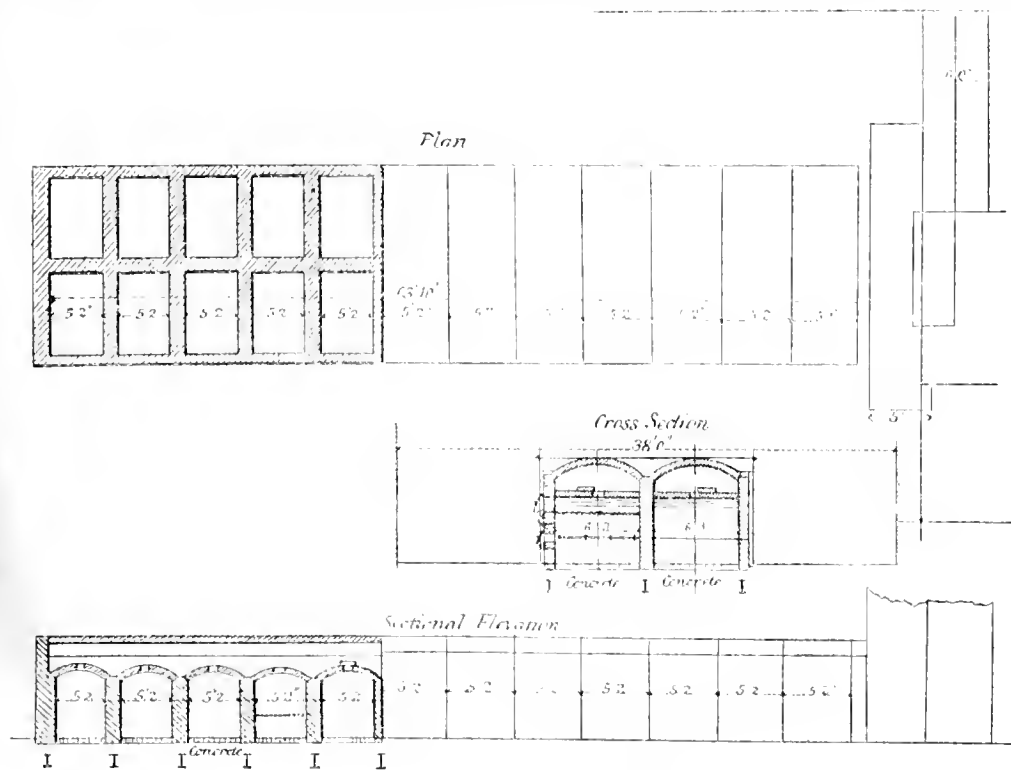

In some cases the two kinds of kilns are combined so that a few dust kilns are built alongside the lump ore kilns to burn off the dust produced in the breaking of the lumps.

Much ingenuity has been expended in the construction of various forms of furnace for burning smalls, but till recently success has been very partial.

The plant is much more expensive, more easily deranged, and more difficult to repair. Generally they consist of a

series of seven or eight beds or shelves, on which the ore is fed from the top through a hopper and gradually raked down lower at regular intervals till the sulphur is burned out, and when withdrawn at the bottom contains only a small percentage of sulphur.

I am informed that in some of these furnaces the smalls of Spanish pyrites have been burned down so low as $1\frac{1}{2}$ per cent. sulphur, though I confess I have not been able to do

LUMP ORE KILNS IN PLAN AND SECTION.

this in our kilns. Still I have burned the ore down to 2½ and 3 per cent. over a period of two or three years. Probably this arises from a difference in construction.

I have here a diagram showing the way in which these dust burners are constructed. They require to be erected in the most substantial manner or they are soon knocked to pieces by continued raking and poking.

When they are built back to back the partition wall is required to be especially strong otherwise the whole affair gradually breaks up and becomes useless. To avoid this I have had the wall built of fire lumps. The beds are constructed thus:—

This method allows of a kiln being easily taken to pieces where one of the beds are broken and replaced by a fresh one, whereas by the kilns with a simple arch it is almost impossible to pull down the structure without breaking the rest of the beds. Every portion of the work requires to be bound together with iron ties in the strongest and most substantial manner, and in our own kilns the ties that go through from end to end are embedded in a groove in the partition wall. I have made a long series of experiments to trace the gradual combustion of the ore from charging at the top to discharging the burnt ore at the bottom, and the following is the average result of a month's working of each bed, an analysis of a sample of each bed being drawn every day for a month.

The charge of ore is put in the kiln once every eight hours, and as there are seven beds, the charge takes 7 × 8 = 56 hours to completely consume the sulphur.

Dust Room—In kilns burning smalls, it is found necessary to make provision for settling out the dust from the shelves, which rises in great quantity when the charge is raked over from one bed to another. A long distance must be traversed before the gas arrives at the Glover tower to give time for its perfect subsidence.

DUST SHELVES.

If this precaution is neglected, the tower would become choked and the draught so much impeded that the process would soon be brought to a stand. There are many ways of accomplishing this, but the diagram shows a very effective arrangement. The flues require cleaning out every two or three years. Notwithstanding all precautions, a certain portion of dust passes into the tower, and, meeting the down current of sulphuric acid, dissolves. A solution of sesqui-

sulphate of iron in sulphuric acid is formed, which again deposits in the cooler, and greatly impedes the refrigeration of the hot acid coming from the tower.

SECTION OF DUST BURNER.

Gases from Kilns.—Being desirous to ascertain the limits of fluctuation in the composition of the gases from the kilns, I have made a long series of trials both upon lump and upon two sets of dust kilns. The gases were in all cases drawn from the flues before reaching the nitre stack and so avoiding the nitre gases.

TABLE No. 1.

SULPHUR TESTS OF PYRITES DUST CONTAINING 50 PER CENT. SULPHUR.

Taken from the top to bottom shelves of a kiln.

Average per Cent. of Sulphur.	November, 23 Trials to each Shelf.	December, 26 Trials to each Shelf.
No. 1 shelf.....	31.27	32.81
No. 2 shelf.....	21.41	17.55
No. 3 shelf.....	12.77	11.60
No. 4 shelf.....	6.59	5.05
No. 5 shelf.....	4.08	3.42
No. 6 shelf.....	2.35	2.56
No. 7 shelf.....	2.27	1.96

The ordinary charge of pyrites was in all cases the same both for lumps and smalls, so that a strict comparison can be made.

It will be observed upon inspecting the table that the fluctuations in the sulphurous acid and oxygen range within extremely narrow limits whether we compare the results from the two sets, dust kilns together, or with the lump ore kilns.

I may state that all through these trials upon different sets of kilns, towers, chambers, &c., they are all of the same capacity, and the charges are of the same weight, so that the results are in almost every respect strictly comparable. The experiments are made on two distinct acid plants, but of exactly similar measurements.

TABLE No. 2.

7.05	8.32				
7.06	8.32				

Temperature of the Kiln Gases.—I have had some little trouble in ascertaining the exact temperature of the gases as they enter the Glover tower.

With lump ore the heat is considerably greater than with dust, the reason being that the distance traversed in this case is very short, whereas in dust kilns a considerable amount of heat is lost by radiation in traversing the long winding chambers forming the dust depositing room.

In a set burning lump ore the heat will melt both lead and zinc but not antimony. Now as zinc melts at 773° F. and antimony at 800° F. it follows that the temperature is between those two numbers. On the other hand the heat of the gases from dust kilns ranges about 610° or thereabouts, sometimes it is rather lower, but it is difficult to test with a mercurial thermometer although I have made many observations in which the heat was not more than 570° to 580° F. Generally it will melt lead which is 620° F.

The Nitre Pots.—In the stack connecting the kilns with the kilns on one side, and the pipe leading to the Glover tower on the other, there is a space in which the pots containing the nitre are placed. There are generally two such pots which are charged alternately with the proper proportion of nitre and sulphuric acid.

I do not like this plan myself, since it is impossible to regulate the heat of the oven. A much preferable arrangement is to fix the pots on the outside and lead the nitric vapours into the stack. This can be so arranged that not the smallest quantity escapes into the air and the heat from a small coke fire being regulated to suit the charge, avoids the difficulty of frequent breakages from the sudden chilling of the nearly red-hot iron pot when a new charge of acid is introduced.

The nitric acid vapours along with the sulphurous acid of the kilns mix and pass together into the Glover tower.

The Glover Tower or Denitrator and Concentrator.—The use of the Glover tower is two-fold, viz.:—1st, To reduce the nitrous act collected at the Gay-Lussac or

absorbing tower (by means of the SO_2 of the kiln gases) and return it to the chambers; and 2nd, to concentrate the weak acid of the chambers and so obtain acid of 150 Tw., suitable for using in the Gay-Lussac tower for absorbing a fresh portion of nitrous acid.

The construction of a Glover tower is very simple. It is a framework of iron lined with lead. This again is lined with acid-proof bricks. The interior is packed either with coke, flints, acid-proof bricks, or with cylinders as in the accompanying diagram. The hot gases pass up, and a stream of nitrous vitriol mixed with weak acid from the chambers passes down. The nitrogen compounds and the steam from concentrating the weak acid pass upwards into the chambers whilst a stream of denitrated and concentrated

GLOVER TOWER DENITRATOR.

acid continually passes down and runs into a cooler at a temperature of 280 to 300° F.

The temperature of the concentrated and denitrated acid which runs from the tower ranges from 285° to 300° F., and depends upon the heat from the kilns and the amount of acid run down the tower.

From lump ore kilns, the amount of concentration greatly exceeds that of the dust kilns, so that in certain cases, as where strong acid is required, this becomes a very important point. In either case, if the towers are well attended to, the quantity and strength being once fixed, the daily feed of nitrous and weak acid ought never to vary.

From a tower 30 ft. high and 10 ft. diameter 26·2 tons of acid of 135° Tw. are concentrated to 150° Tw., producing 23·8 tons of 150° Tw., and 2·4 tons of water evaporated; and in addition 21 tons of nitrous vitriol are heated from 80° F. to 300° F. if heated by lump ore kilns in which the

gases are delivered direct to the tower; but from the same weight of pyrites sends the gases from which pass through the long dust chamber and by consequence lose a great amount of heat by radiation in their passage to the tower, not more than 16 tons of acid of 135° Tw. are concentrated to 150° Tw., producing 14·29 tons of acid 150° Tw., and 1·71 tons of water evaporated; and in addition 21 tons of nitrous vitriol are heated from 80° F. to 280° to 290°.

The hotter gas of the lump ore kilns produces more steam than the dust kilns and at times tends to reduce the first to second chamber drip so low as to keep the last chamber pale, unless a larger portion of nitre is used. On the other hand, while occasionally a somewhat lower consumption of nitre occurs in the dust burners, a much smaller proportion of strong acid is produced as already stated.

The effect of this difference in evaporation of water is that the lump ore kilns do not require steam to be thrown

into the first chamber, whilst the dust set always requires the addition of steam.

The height of the Glover tower attached to the lump ore kilns is 30 ft. and 10 ft. diameter.

The height of the tower connected with the dust kilns is 42 ft. and 10 ft. diameter.

What are called the "old dust burners," is a set attached to the tower of the present lump ore kilns and which were pulled down.

Originally these two towers were of the same height, but, with a view to lowering the temperature of the gases passing into the first chamber, we increased the height by 12 ft. The result was not so satisfactory as we desired, the reduction of temperature only amounted to about 10° instead of 30° or 40°.

The tower burning lump ore delivers its gases into the first chamber at an average temperature of 202° F., whilst the high tower connected with dust burners delivers the gases at about 190° F.

Indeed, I scarcely think even this diminution is all ascribable to the height of the tower, but rather to the low temperature of the kiln gases entering the tower. This confirms an opinion of Dr. Atbleck expressed some time ago.

Extract from Dr. Atbleck's address to the Tyne Chemical Society. He says:

"I consider, in fact, that in such cases the upper part of the tower undoes to some extent what has been done in the lower and hotter part. The steam evaporated from the acid in the lower and middle sections of the tower and carried along by the hot gases in their passage upwards, is partly condensed again, when they have been cooled down below the boiling point, by the colder stream of acid they encounter near the top. And thus less concentration is effected than would be if the gases were allowed to escape from the tower at a temperature more approaching the boiling point, or say 200° F. And this result would be equally produced by a too high or too closely packed tower, the cooling effect on the gases being the same. Hence it follows that a tower might be made so high as to have practically no concentrating power at all, the gases being cooled at the outlet to near the temperature of the air, and the cold acid poured on at the top running away at the bottom hot, but not increased in strength. This view has been confirmed by the improved concentration along with freer draught, obtained by working with short towers of about 18 ft. in height, and by diminishing the packed space in higher ones in various works in the neighbourhood."

So much for Dr. Atbleck.

But I cannot quite understand from these remarks whether he means 18 ft. from the top of the tower to the bottom of the saucer, or 18 ft. of working space, which would make the tower about 25 ft. high. There is some difficulty in getting the exact temperature of the gases entering the towers, but, as already stated, there is about 150° difference between that of the lump kilns and the dust burners.

The Cooler. As the temperature of the acid running from the Glover tower is so high as 280° to 300° F., it is necessary to cool it to as near the temperature of the air as possible. Various contrivances have been adopted to effect this; some makers pass the acid through lead pipes surrounded with water, the objection to which and some other forms is the difficulty of cleaning the deposit which invariably forms after a short time, and which stops the pipes and protects the acid from the cooling by the water in which the pipes are laid. This is especially the case with acid made from pyrites smalls. A thick coating is formed on the surface of the lead.

I have here a diagram of an open cooler which answers better than the tubes because it allows of cleaning while in use. You will see that the acid and the current of cooling water run in opposite directions, and there is also a current running underneath the lead. It is 11 ft. long and 9 ft. wide. It has 12 double channels for acid, so that the acid travels in all about 500 ft., and as there are two coolers it travels about 1,000 ft., and the cooled acid runs out at a temperature of from 83° to 120° F. By the annexed table you will see the progress of the cooling as the acid travels

from one channel to another. Two of these coolers will reduce the temperature of 38 to 40 tons of acid of 150° Tw. —1·750 sp. gr.—from 300° F. to from 83° to 120° F.,

COOLER FOR ACID FROM GLOVER TOWER.

depending on the season of the year, being 180° per 24 hours. The further cooling takes place in the store tanks. The acid cools more slowly as the temperature approximates to the temperature of the water used for refrigeration, as may be seen by the diagram showing the amount of fall in temperature in each successive channel. From 280° to 216° the fall is very rapid, but from 216° F. the—

Chambers.—The chambers on which I have made observations are two sets of four.

Each chamber is 130 ft. long, 20 ft. wide, and 16½ ft. high. 12,000 cb. ft. per chamber, working with about 19 to 20 cb. ft. of space to 1 lb. of sulphur charged per 24 hours.

After passing through the Glover tower and as it enters the first chamber the gas has a temperature of between 189° and 203° F. (according to whether it is from lumps or dust).

At the extreme end of the pipe from the last chamber to the Gay-Lussac tower there is a further fall of about 28° F. in the exit gases.

These gases, consisting of nitrogen, oxygen, nitrous acid and small quantities of sulphurous and sulphuric acid, then pass up the Gay-Lussac tower, and in their passage undergo partial absorption.

From this diagram it will be seen that the average fall in temperature in passing from the entrance of No. 1 chamber to the extreme end of the chamber was:—

TABLE NO. 4.

Entering Gay-Lussac	3	4
Exit from Gay-Lussac	4	5

The diminution in temperature arises from diminution of chemical action in the successive chambers, so that roughly the temperature is an exponent of the quantity of acid produced in each chamber.

You will observe by the diagram plotted that I have recorded the maximum and minimum temperatures of the air, and you will, I think, see that the rise or fall of temperature in the chambers is more or less affected by external circumstances. This fall in temperature fluctuates within well defined limits, it depends partly on the diminution of chemical action in the chambers, and partly on the external temperature of the air; in summer it rises, in winter it falls.

The observations were not taken inside the chambers, but in the pipe leading from one chamber to the other. This appears to be a much more accurate way of getting the average either of temperature or composition of the gases.

The method by which the progress of the operation is observed and controlled consists in noting the colour of the gases in the last chamber, which should always be a dark brownish red indicating the predominance of nitrous acid, and by constantly noting the specific gravity of the acid which collects in the drip glasses.

It is customary at most works to collect the samples of acid from the sides of the chambers, but this is generally a very slow progress. I find it much better to obtain the drips from the pipes connecting the chambers together, because the flow of acid is much more rapid and the indications consequently much more instantaneous. A large test glass can easily be filled in a few minutes, whereas if drawn from the sides of chambers, hours are sometimes required to get sufficient acid for a single test.

For a set of four chambers the drips should stand as follows:—

TABLE NO. 5.

NORMAL DRIPS.

Drip from tower to 1st chamber	95 to 105
Drip from No. 1 to No. 2 chamber	130
Drip from No. 2 to No. 3 chamber	122
Drip from No. 3 to No. 4 chamber	105
Drip from No. 4 to Gay-Lussac	85

The drip from No. 1 to No. 2 should never stand lower than 130°. If it does so the consumption of nitre is increased. This, however, cannot always be avoided if the tower is producing an excess of steam.

The strength of the acid made in the chambers (of which the drips are the indicators) is increased or diminished according to the supply of steam, derived partly from the weak acid which is undergoing concentration in the Glover tower, and partly from jets of steam thrown into each chamber. Great difficulty is often experienced in regulating the strength of the first chamber, but it is upon the

proper regulation of this strength that the working of the subsequent ones depend.

If the kiln gases are too hot an increased evaporation of water from the tower takes place, and keeps down the strength of the drip considerably below 130°. In that case a high consumption of nitre is sure to take place.

The composition of the gases as they pass from one chamber to the other is shown in the following table:—

Gay-Lussac Tower or Absorber.—This tower is used for the purpose of economising the consumption of nitrate of soda by collecting the spent nitrous acid as it passes out of the last chamber.

GAY-LUSSAC OR ABSORBING TOWER.

SKETCH SHOWING THE CONSECUTIVE ORDER OF THE PROCESSES.

Before the invention of this tower there was required from 8 to 10 lb. of nitre to every 100 lb. of sulphur consumed. By the use of this contrivance the consumption may be reduced to from 2 to 3 lb.

The operation consists simply in allowing the waste gases from the last chamber to draught through this tower which is packed with hard engine coke and down which a stream of strong acid of 1.50 Tw. is continually running.

The waste nitrous acid vapours are absorbed in their passage up through the tower by the strong acid, which runs

into a cistern and is returned to the Glover tower and used instead of so much fresh nitrate.

The construction of a Gay-Lussac tower is as simple as the Glover tower. It is merely a wooden framework lined with lead, the inside being again lined with bricks. It stands 46 ft. high. There is a series of bars or an arch with suitable openings for allowing the spent gases to pass through, and on this arch to the top of the tower the space, as already stated, is packed with coke.

The spent gases from the last chamber in entering this tower generally contain 3 to 4 grains of acidity reckoned as SO_3 , but in passing out only about 1 to 2 grains, consisting of SO_2 , SO_3 , and nitrous acid not absorbed. They contain also 6 to 7 per cent. by volume of oxygen, the rest being nitrogen. There is a curious observation with reference to the oxygen, viz., that the gases always contain a small proportion more oxygen in passing out than they contained in entering the tower.

Formerly I ascribed this to some possible leakage of air inwards, but on reconsideration I think it may be caused by the removal of the sulphurous acid and consequent diminution of volume, thereby slightly raising the percentage of oxygen; or, again, it may arise from some decomposition of the oxides of nitrogen, by which oxygen is eliminated, but it always takes place.

The total amount of acidity remaining in the exit gas as it passes to the chimney is a matter of very great importance, since it is an indication as to the working of the chambers.

If the exit contains more than 1 to 2 grains of acidity it indicates that sulphurous acid is getting into the absorbing tower, the result of which is the reduction of the nitrous acid and consequent loss of nitre.

Under the Alkali Act, also, not more than 4 grains of acidity per cubic foot of gas are allowed to be passed into the air, any excess resulting in a notification from the Government inspector that you are exceeding the limit allowed.

By a daily comparison of the temperature of the acid which is poured into the tower with the temperature as it runs out at bottom the heat will be found in many cases to diminish, but more frequently to increase. The explanation of the increase is probably to be found in the greater or less quantity of SO_2 in the spent gases, but more particularly in the greater or smaller quantity of moisture accompanying the gases.

An excess of moisture passing into the absorbing tower and coming in contact with strong sulphuric acid, raises the temperature considerably, as well as causing the disengagement of nitrous acid.

Table No. 9 shows the average temperature of the acid at the point where it runs into the distributor on top of the tower, and the corresponding temperature when it arrives at the bottom and passes into the store tank. The plus or minus sign shows the amount of rise or fall in temperature.

Since the temperature of the chamber exit gas is usually lower than the temperature of the acid running into or out from the tower, it would seem that other causes are in operation to produce the increased temperature.

The daily testing of the acid running out of this tower is an absolute necessity in order to know how the absorption of nitrous acid is proceeding. The usual method is by a standard solution of permanganate of potash, or by working with Dr. Lange's nitrometer.

Of course it is necessary to arrange that the same quantity of strong acid is poured down the tower every hour, otherwise the results must be quite fallacious. We use a standard solution of permanganate, of which 100 cc. are equivalent to 0'1900 N_2O_5 , and we find the chambers continue in good working order so long as 10 cc. = 175 grains of the nitrous acid vitriol continues to require from 60 to 80 cc. of permanganate. If less than 60 cc., we increase it. This strength (say 75) represents about 0'8142 per cent. N_2O_5 = 18'238 lb. per ton or = 1'157 per cent. nitrate of soda, or 48 lb. NaNO_3 per ton.

Now, as we pour down 21 tons of 150 acid in 24 hours = 12 eggs, at $\frac{1}{4}$ tons, the total nitrous acid absorbed during the day will be equal to about 857 lb. nitrate of soda.

It is the general opinion of vitriol manufacturers that the temperature of the acid poured down the Gay-Lussac tower should be as low as it is possible to cool it, in order that the absorption of nitrous acid may be complete. It will be in the recollection of members of this Society that I

expressed some doubts about the necessity of these precautions at one of our meetings.

I drew your attention to the difference between some kinds of absorption and others, and I instanced the case of a tower down which hot acid was poured and up which ammonia gas was passed. Here it was clear that the combination would be instantaneous without regard to temperature.

		90	94 + 1		
		71	71 + 3		

On the other hand, I instanced a tower down which water was passed and carbonic acid passed up. Unless the water was exceedingly cold, little absorption would take place, whilst heat would be quite fatal to combination.

Comparing these two operations, I considered that nitrous acid and strong sulphuric acid belonged to the first category, since when once combined they cannot be separated even upon boiling. I had tried this experiment. But Mr. Newlands reminded me that I had not tried the converse experiment, viz., passing nitrous acid into hot sulphuric acid. I have recently made some experiments with a view to determining this question, and the following are the results.

In order to obtain results on a small scale comparable with those of the Gay-Lussac tower, it must be borne in mind that the proportion of nitrous acid in the spent gases from the chambers is exceedingly small, and therefore many hours are required to produce an acid of corresponding strength to the nitrous vitriol from the tower if it really is absorbed at all.

The first experiments were made to ascertain whether absorption of nitrous acid would take place at all, at a temperature of 212° F.

For this purpose I obtained two sets of absorbing bulbs such as are here exhibited. These were inserted into a leaden box, with a cover in two halves. A pipe for

inserting a jet of steam and another for the exit of steam was used for heating water surrounding the bulbs to 212°, and a thermometer was inserted to note temperature.

An india rubber tube connected with the pipe entering the Gay-Lussac tower supplied the gases which were drawn therefrom and through the bulbs, filled with 70 cc. of acid of 150° Tw. by means of an aspirator.

The pump was kept working from 8 to 24 hours in the various experiments. When the trial was completed the bulbs were detached, the acid poured out, and a portion tested for nitrous acid in the usual way with standard solution of permanganate. The remainder of the acid was placed in a small retort and heated to boiling for some time, allowed to cool and again tested with standard permanganate to ascertain whether it had lost its nitrous acid. A corresponding experiment was made at the ordinary temperature of the air, and the product tested as before.

The preliminary trials were made with only one set of bulbs. It was found necessary afterwards to add further absorption bulbs. The results are as follows:—

I made six experiments to ascertain if acid of 150° Tw. would absorb the nitrous gases from the tower at a temperature of 212° F.

TABLE No. 10.

COMPARATIVE RESULTS OF PASSING THE NITROUS GAS THROUGH 70 CC. OF 150° TW. ACID DURING A PERIOD OF 12 HOURS.

At the Temperature of 212° F.		At the Temperature of 50° F.	
	N ₂ O ₅ .		N ₂ O ₅ .
	0.4788		0.5320
	0.5054		0.6118
	0.5433	70 cc. absorbed	0.6004
70 cc. absorbed	0.5852		0.7448
	0.5985		0.8512
	0.6216		

A B Nitrous vitriol from the absorbing tower contains from 0.7980 to 1.0640 grms. N₂O₅ in 70 cc.

This led me to conclude that the absorption was at any rate very considerable, even at so high a temperature as 212° F., a temperature far higher than any heat that is likely to be used in an absorbing tower.

As the current of gas, although passing through the acid for equal times, might vary in rapidity and therefore in quantity, I arranged a fresh series of trials, in which the amount of gas was measured by means of an aspirator during 12 hours, and in order to ascertain whether any nitrous or other acid gas escaped absorption, I used a third absorption bulb of acid, and finally a set of bulbs containing a standard solution of caustic soda to remove the last traces of acidity of any kind.

During the period of 12 hours about four to five cubic feet of gas passed through the absorbing apparatus. The results were as follows:—

TABLE 11.

COMPARATIVE RESULTS OF PASSING THE NITROUS GAS THROUGH 110 CC. OF 150° TW. ACID DURING 12 HOURS AT THE TEMPERATURES OF 212° AND 50° F.

At 212° F.

Cubic Feet passed through in 12 Hours.	N ₂ O ₅ Absorbed in 110 cc.	Grammes of N ₂ O ₅ Absorbed from 1 lb. of Gas.	Grammes of N ₂ O ₅ Escaped and Re-absorbed in Cold Acid.	Grains of Acidity as SO ₃ Absorbed by NaOH.

5.3	0.8778	0.1654	0.00097	0.70
5.3

It would appear from a comparison of these results that the absorption at so high a temperature as 212° F. goes on almost as energetically as when the gas is passed through cold acid, and confirms the opinion I had formed that such would probably be found to be the case on trial.

Nevertheless, I would by no means advocate the use of very hot acid at the towers because there are other reasons against it, such as the rapid destruction of the lead of the plant. I merely wish to show that during hot weather there does not seem to be any reason for adopting extra or special methods for cooling the acid before passing it down the absorbing tower, and that when an increased consumption of nitre takes place the cause must be sought elsewhere, and not in the higher temperature of the acid.

In working a set of chambers and towers there are certain indications which may be regarded as prophetic of a coming change. The derangement of the working can frequently be averted by attention to these indications, viz. :—

1. A considerable and continuous fall in the percentage of nitrous acid in the nitrous vitriol from the Gay-Lussac tower.

2. A considerable rise in temperature in the acid from the Gay-Lussac.

3. A rise in the quantity of SO₂ in the exit gases; and

4. When the change has taken place the gases of the last chamber become colourless.

When the chamber acid becomes sulphurous a reddish precipitate forms, due to the separation of selenium, of which I have here a specimen.

I have now traced the operations of manufacturing sulphuric acid through all the stages of its progress, from the production of sulphurous acid at the kilns and the nitric acid which mixes with it and passes together into the Glover tower, from thence to the chambers and on to the Gay-Lussac absorbing tower, and finally the exit of the spent gas.

The observations I have made, and which you will see in the tables have involved an immense amount of work which has been carried on for years—for you will please observe that each of these figures are not single observations but are mostly the average daily results of a month's work, and therefore amount in each table to hundreds.

To me, they have thrown light upon many questions about which I was unacquainted and which have considerably helped me in my daily work, and it was with a feeling that they might possibly help some of my younger professional brethren who may be in charge of vitriol works, and who may not have similar opportunities for this study, that I have collected and systematised this work which I now lay before you, and which I trust will prove to be "memoranda for the use of somebody." I am only too sensible that I have but touched the fringe of a very large and interesting subject, but the time allotted for such a paper will not admit of further elucidation. On some future occasion I hope to take up some other points on which I have been unable to dwell this evening.

DISCUSSION.

The CHAIRMAN, in inviting discussion, said that it would probably be very interesting to those who were concerned in the production of vitriol to compare the paper with the historic work of Lunge, and thus see how far his researches were confirmed by the most recent work on the large scale. He wished especially to direct the attention of members to the elaborate series of results which Mr. Crowder had brought before them in the form of diagrams. It ought, he thought, to be clear to the younger technologists among them that no amount of trouble was too great for the

purpose of arriving at information and results which in these days of competition were absolutely necessary to success. That lesson, if no other, might certainly be drawn from the series of results which Mr. Crowder had brought before them.

THE CHEMISTRY OF WHISKY AND ALLIED PRODUCTS.

BY ALFRED D. ALLEN.

IN this paper I propose to include, with some original observations, a number of facts and figures I have collated from various sources, believing that I shall be doing a service to others and spare them much of the trouble I have had in collecting the information. I must premise that this paper is one on the *chemistry* of whisky, and I do not propose to discuss the technical details of the manufacture of spirit, except in so far as they may be supposed to have an influence on the composition of the products obtained.

The process of manufacturing malt whisky as practised in the Highlands of Scotland commences with the malting of the barley. The product is dried for two days on perforated tile or wire floors, through the holes in which pass the products of combustion of a fire chiefly or entirely fed with peat. The dried malt is crushed between metal rollers and treated with hot water in a mash tun in much the same manner as in a brewery. The initial temperature of the water in mashing is commonly about 160° F., the next quantity being at 170°, and the third at 180°—185° F.; but of course the temperatures vary within certain limits at every distillery.

The *draff* or *spent grain* has much the same composition as brewery grains, and finds a ready sale as a cattle food to the farmers in the neighbourhood of the distilleries. When wet, the draff usually contains from 75 to 78 per cent. of water.

Following are the results yielded by two samples of dried grains from pure malt distilleries, analysed in my laboratory :—

	Spent Grains from Malt.	
	Per Cent.	Per Cent.
Moisture	10.32	8.00
Oil	6.70	5.05
*Proteids or albuminoids	19.88	19.80
Sugar, starch, digestible fibre, &c. ...	41.06	49.66
Woody fibre	19.00	13.16
Mineral matter (ash)	3.91	4.31
	100.00	100.00
*Containing nitrogen	3.14	3.13

The wort is cooled to about 70 to 80° F. as quickly as possible, to prevent it becoming soured or "blinded," and is then fermented with brewers' yeast, the fermentation being pushed much further than in the brewing of beer. The fermented wort, technically called "wash," is then transferred to the wash-charger and thence to the wash-still.

The distillation of the wash is conducted in the Highland malt whisky distilleries in what is known as a "pot-still." This is simply a copper still, with head or capital and worm of copper, without any special fractionating arrangement. It is furnished with a mechanical stirrer, which is necessary to prevent the particles of solid matter settling on the bottom and becoming charred by the open fire by which the still is heated. In some distilleries about 1 lb. of soap is

added for every 100 gallons of the wash, to prevent frothing. The Highland pot-stills have a capacity usually ranging from 6 to 12 thousand gallons.

The first product obtained by distillation of the wash is a weak alcoholic liquid called *low wines* or "singlings." The residue left in the retort is known as *pot ale* or *burnt ale*, and is run to waste. After separating the suspended matter the pot ale contains, according to my friend Mr. C. F. Cross, about 3 per cent of solid matter, consisting of about 1 per cent. of lactic and other acids, 0.7 of peptones and other nitrogenous matters, 0.6 of non-nitrogenous extractive matters, and 0.7 of mineral matters, in which phosphates predominate. I understand that the utilisation of this product is likely to be effected very shortly, if not already accomplished.

The "low wines," or first product of the distillation of the wash, is then subjected to a second distillation in a still just like that used in the first operation, except that it is not provided with an agitator. The products of this second distillation are:—

1. Foreshots;
2. Clean spirit or whisky;
3. Feints; and
4. Spent lees.

The spent lees are run away. The foreshots and feints both become milky when diluted with an equal measure of water, and this behaviour is employed to ascertain the time when the distillate should be diverted from one receiver to another. In some distilleries the specific gravity is taken as the indication of the end of the second stage, clean spirit being run until the distillate has a strength varying from 10 over proof to less than proof, according to the practice of the works. The third fraction is run till the distillate contains a very trifling proportion of spirit (2 to 3 %).

The foreshots and feints obtained in the foregoing process are returned to the low wines still, and hence redistilled with the low wines of the next period. Hence the only distillate which is ultimately obtained is the clean spirit or whisky. No fuel-oil or other secondary distillate is ever obtained when working with the pot still.

The clean spirit or new whisky manufactured in pot-stills has usually an alcoholic strength ranging from 13 to 50 over proof, but is usually reduced in Scotland to 11 over proof and in Ireland to 25 over proof, before bottling.

When new, pot still whisky has a disagreeable, and in some cases extremely nauseous, flavour. But this gradually disappears by storing in casks, the improvement being usually attributed to changes produced by oxidation in the pores of the wood. Sherry casks are preferred to plain wood casks for storing whisky. The wood is in all cases oak, and usually American oak.

The loss of alcohol by keeping in wood varies much with the condition of the warehouse, being greatest where the atmosphere is moist. It is estimated by the Excise to average 2½ per cent. of proof spirit in the first year, nearly 1 per cent. in 3 years, and from 6 to 8 per cent. in 5 years.

The improvement of pot-still whisky by ageing continues for a number of years, and it is an interesting fact that some brands of whisky which are the finest in the market when matured, are when raw of the rankest and most nauseous flavour. The flavours of many makes of malt whisky are peculiar and perfectly distinctive, and can be recognised by an expert even when blended with the products of several other distilleries. The whiskies made in pot-stills in Islay and the West of Scotland are usually stronger in flavour than the whisky distilled in Glenlivet and the neighbourhood of Elgin and Inverness.

Scotch pot-still whisky differs from Irish pot-still whisky in the fact that the malt is dried by means of peat, and that malted barley is practically the only grain used. With the exception of two distilleries in the North of Ireland, Irish pot-still whisky is distilled from a mixture of malted and unmalted barley, with the addition in some cases of a small proportion of other grains.

"Potteen," by which is meant the spirit made in illicit stills, is a product almost peculiar to Ireland, where 1,739 detections of illicit stills occurred in 1889, whereas there were only 31 cases of the sort in Scotland and 11 in England

in the same year.* Most of these distilleries were very small affairs, but considering that the duty on spirit is 10s. 6d. per proof gallon, while the cost of production is only a few shillings, and that it is a very easy matter, with very imperfect appliances, to distil 5 or 10 gallons a day, there is considerable pecuniary inducement to practice the art, to say nothing of the pleasure to be derived from cheating the Government and hoodwinking the police. In many, probably the majority of cases, Irish potteen is distilled from fermented molasses, and not from malt, as is commonly supposed. It is therefore more nearly allied to rum than the whisky proper. It is said to be a common practice to put a lump of peat in the still "For the sake of old Ireland."

Rum was formerly made by distilling the fermented juice of the sugar cane, but is now a spirit distilled from fermented molasses, or other residual products of the manufacture of sugar either from the sugar-cane or beetroot. The most common source is the "megass" or crushed cane, from which the juice has been expressed by means of rollers. This retains from 8 to 10 per cent. of sugar and 50 per cent of water, and hence is an admirable source of spirit. The flavour of rum is said to be chiefly due to the presence of butyrate and acetate of ethyl.

Brandy is a term properly applied to the spirit obtained by distilling fermented grape sugar, whether as contained in the wine or fermented grape juice itself, or in that which it retained by the skins of the fruit after the juice has been expressed. Of course, the latter is the ordinary source of brandy. The word "brandy" is evidently a corruption of *Brantwein*, which may be translated as "burnt" or "distilled wine." But the term is now extended in its application so as to include the spirit distilled from maize, rice and other cereals, potatoes, turnips, beetroot, molasses, &c., all of which are lumped together under the comprehensive name of "*Brantwein*." This word is unfortunately commonly translated as "brandy," thus wrenching the word from its original and proper meaning, and causing serious confusion in the definition of brandy.† Wine-brandy, like whisky, owes its flavour to the presence of certain bodies which undergo a marked change by ageing. In fact, wine-brandy and pot-still whisky, and perhaps rum, are the only kinds of spirits extensively manufactured which undergo marked improvement by maturing, apart from the modification in flavour which may be produced by the sherry or other liquid previously stored in the cask.

Pot still whisky, rum, and real brandy are all produced in stills of simple construction and so designed as to prevent rather than encourage the removal of the subsidiary ingredients by fractionation. On the other hand, the various kinds of fractionating still, of which the Coffey still is the

* A large illicit distillery was discovered in Birnigham in 1889. In addition to defrauding the revenue, the condensors in this manufacture stole the gas they required by tapping the main, and are still undergoing punishment for this offence.

† The *Beltoner Bienen-Zeitung* asks: "What do they understand by the word 'Cognac' in France?" and says: "The district of Charente is the place of origin of real 'Cognac' and has, during the last seven years, produced an annual average of 20,000 hectolitres, while the annual export by France of liquor known as 'Cognac' has exceeded seven times this quantity. In trade we usually understand by 'Cognac' a brandy obtained by the distillation of wine, and which was formerly known as *Fruchtbrandwein*, that is, 'Fruit brandy'; but it has been shown by analysis, as also in a bulky volume issued by the State Department of Hygiene, that there is no reliable means of distinguishing real brandy as distilled from wine from the spurious stuff. It will, nevertheless, be interesting to those in the trade to learn the decision of a French court of law as to what it understands by the word 'Cognac.' A merchant of Angoulême who bought brandy in Valenciennes and labelled it 'Cognac,' was prosecuted for so doing, but was acquitted on the ground that the word 'Cognac' is not to be exclusively understood as descriptive of the place of production, but often, as in the present instance, as descriptive of the nature of the product. According to this decision, it is, then, to be regarded as sufficient when labels announce the nature of goods to which they are affixed, and it is not requisite that the contents of a bottle should have been produced in the place mentioned on the label. This fundamental decision is, however, not consistent with sentences pronounced by various French law courts upon manufacturers of sparkling wines, who have been heavily fined for introducing into trade wines which they described as 'champagne,' and which had undergone a similar process to that of the genuine article, but had not been made from wine grown in the champagne district."

best known and most widely used, aim at the removal of the subsidiary constituents of the spirit, economy of fuel, and the production of an alcohol of high strength and comparatively great chemical purity. In fact, spirit is obtained in the patent still at one operation, as strong as 55° to 70° over proof.* The purest spirit of the patent still (chemically speaking) is known as "silent spirit," as its odour and flavour give no indication of its origin; but unless the process is very carefully conducted the spirit is liable to retain sufficient odour or flavour to enable an expert to distinguish it as derived from potatoes, beetroot, grain, &c., as the case may be. In fact, the patent-still spirits manufactured in Ireland and the South of Scotland possess some of the characters of whisky, which the true silent spirit made in Germany does not.

In the manufacture of spirit in the patent still, unmixed malt is never employed. In the United Kingdom a mixture of unmalted barley, rice, maize, and other cereals is employed, together with the minimum of malt requisite to furnish the diastase for the conversion of the starch of the unmalted grains. Hence, apart from the differentiation effected by the fractionating still, the materials used for producing spirit in the patent still differ in a marked manner from the pure malt or mixture of malted and unmalted barley almost exclusively used for manufacturing whisky in the pot-still. The patent-still spirit is much milder in flavour than the pot-still product, and does not

undergo so great a change by ageing, though of course it is just as liable to take up flavouring matters from the cask in which it is stored, and may undergo more or less change by oxidation. But its different origin and characters and the comparatively low cost of its production appear to be fair grounds for the contention of the Highland distillers that the present practice of blending pure malt pot-still whisky with from one to ten times as much patent spirit ought not to be allowed, as at present, to be conducted in bond under excise supervision (or what Mr. Healy calls "under the very nose of the lion and the unicorn"), and the resultant mixture ought not to be sold, as it frequently is at present, as "pure malt whisky."

Potatoes, turnips and other roots, and acid-made glucose are not employed in this country for the manufacture of any kind of spirit, though they are largely used on the Continent. Foreign silent spirit is imported to a considerable extent, though not so largely as is commonly supposed, the total amount imported during the year ending March 1890 being 1,791,386 proof gallons. A considerable proportion of this was used for methylating.

I have compiled the following tables relating to the production of whisky during the year ending 30th September 1889, from the figures given in evidence in July last, by the officials of the Inland Revenue Department, before the House of Commons Committee on British and Foreign spirits.

Distilleries using	England.	Scotland.	Ireland.	Total.
Pot-stills only { Number	None†	113	22	135
{ Produce	None	7,367,727	5,745,564	13,113,291
Both pot and patent stills { Produce	1,482,282	4,745,672	3,665,210	{ Pot 2,086,509
{ Number	10	13	8	{ Patent 7,866,645
Patent stills only { Number				31
{ Produce	7,026,740	7,301,678	1,993,813	16,322,231

ANNUAL PRODUCTION OF BRITISH SPIRITS.

	Gallons.
Pot-still whisky	15,200,000
Patent still spirits sold as whisky	6,028,284
Patent still spirits sold as gin, brandy, &c. ..	6,000,000
Spirits consumed as beverages	27,828,284
Retained in bond	6,194,135
Exported	3,371,396
Methylated	1,118,361
Wasted	2,010,038
	117,084
Total	40,960,205

IMPORTATION OF FOREIGN SPIRITS IN 1889.

	Gallons.
Brandy	2,858,774
Rum	1,087,109
Geneva	304,493
Unenumerated unsweetened spirits	3,199,470
Unenumerated sweetened or mixed spirits ..	84,275
Total	10,534,091

During the year ending 30th September 1889, the following quantities of materials were used in the United Kingdom for the production of spirits:—

Material.	Quantity.	Capable of producing, Proof Spirit.
Malt	907,971 quarters‡	18 gallons per quarter.
Unmalted grain	1,655,222 quarters	24 gallons per quarter.
Sugar	31,152 cwt.	10 gallons per cwt.
Molasses	211,161 cwt.	7 gallons per cwt.
Rice	57,721 cwt.	7½ gallons per cwt.
Jawarree	8,898 cwt.	1½ gallons per cwt.

The distilleries using malt alone number 115, of which 113 are in Scotland (corresponding to the distilleries using pot-stills only), and two in Ireland. The distilleries where mixed malt and unmalted grain are used number 42, while five distilleries use sugar and molasses in addition, and four employ rice as well. But it must be remembered that the majority of the malt distilleries produce comparatively small quantities of whisky, while the distilleries making patent-still spirit are in most cases of enormous producing capacity, so that the total production of patent-still spirit considerably exceeds that of pot-still whisky.

With regard to the actual composition of spirits apart from their alcoholic strength, it is well known that alcohol and carbonic acid are by no means the sole products of fermentation by yeast. Pasteur recognised succinic acid and glycerin as constant products of alcoholic fermentation,

* "Rectified spirit B.P." contains 155.45 per cent. of proof spirit, or is 55° 45' over proof. Absolute alcohol is 75° 25' over proof.

† There are no distilleries in England where pot-still spirit only is manufactured, but two distilleries have pot-stills in addition to patent stills.

‡ A quarter of malted barley weighs from 300 lb. to 334 lb.

and the higher homologues of ethyl alcohol are also known to be present in small but distinct amount.* Even the species of ferment affects the character of the product, the *saccharomyces cerevisia* of ordinary brewers' yeast producing subsidiary products distinctly different from those of the *saccharomyces ellipsoides*, which is the ferment of grapeskins. In fact it has been found that by adding the latter ferment to molasses and other saccharine liquids distinct from grape-juice, the product of the fermentation after distillation has all the characters of cognac brandy. The most marked distinction between the products of the two ferments is that whereas in the case of the grape-juice ferment normal butyl alcohol results, in other cases this is replaced by iso-butyl alcohol. Of course the proportion of higher alcohols to be found in the spirit itself is very small, but they become concentrated on fractionation, and hence constitute the greater part of the fusel oil which is obtained from the last runnings. Thus, by the fractional distillation of cognac brandy 25 years old, Ordonneau obtained the following substances (Compt. Rend. 102, 217):—

	Grams. per 100 litres.
Normal propyl alcohol.....	10.0
Normal butyl alcohol.....	218.6
Amyl alcohol.....	87.8
Hexyl alcohol.....	0.6
Heptyl alcohol.....	1.5
Ethyl acetate.....	35.0
Ethyl propionate, butyrate, and caproate.....	3.0
Oenanthe ether (scent).....	1.0
Aldehyde.....	3.0
Acetyl.....	Traces
Amines.....	Traces

Ordonneau's results have been substantially confirmed by Clandon and Morin (Compt. Rend. 104, 1187), who found the percentage composition of the same fusel oil to be as follows:—

	Clandon and Morin.	Ordonneau.
Propyl alcohol.....	11.9	11.7
Normal butyl alcohol.....	19.3	63.8
Iso-butyl alcohol.....	4.5	0.0
Amyl alcohol.....	34.4	21.5

The following proportions of various alcohols, &c. were obtained by Rabuteau (Compt. Rend. 87, 501) from one litre of potato fusel oil:

	cc.
Iso-propyl alcohol.....	150
Normal propyl alcohol.....	30
Iso-butyl alcohol.....	50
Normal butyl alcohol.....	65
Methyl-propyl carbamate.....	60
Isoamyl alcohol.....	27.5
Products boiling above 132 and retaining amylic alcohol.....	150
Ethyl alcohol, aldehyde, and ethyl acetate.....	75
Water.....	125

Trimethyl carbinol also appears to have been present.

The fusel oil from Chicago, produced from a spirit derived from maize, with smaller quantities of other grains, has been examined by Long and Lanchester (American Jour. Anal. Chem. January 1890). The specific gravity of the water-saturated oil was 0.810 at 20°C. It was found impossible to dry it completely by anhydrous sulphate of copper, but a subsequent treatment for two hours at 40–50°C. with dry potassium carbonate removed the remainder of the water. Only a very inconsiderable portion of the oil boiled at a higher temperature than 133°C. It consisted in part of alcohols, and in part of bodies of an

etheral nature, the amounts of the latter being too small for identification. About three-fourths of the sample consisted of a mixture of inactive and active amylic alcohols, with possibly some of the isomeric methyl-propyl-carbinol. Iso-butyl alcohol appeared to be present in next largest amount, and after that iso-propyl and ethyl alcohols, with traces of normal propyl and normal butyl alcohols.

From these results it is evident that fusel oil varies considerably in composition. This will be apparent also, on examination of the specimens before you, which include fusel oil from beetroots-spirit, potato-spirit, and from grain-spirit of Scotch and Irish manufacture. As already mentioned, fusel oil from pot-still whisky is not produced on a commercial scale, and probably has never been seen in quantities greater than would be extracted by a chemist in the laboratory; and as the proportion present does not exceed 0.1 per cent. the quantity isolated has been very small.

Many attempts have been made to estimate with tolerable accuracy the fusel oil in spirits. Of the physical processes, that of Röse, as modified by Herzfeld, is the one which has met with most favour. It consists in diluting the spirit until it contains 30 per cent. of alcohol by weight, and this must be done so exactly that the error is not more than .01 per cent. in deficiency or excess. This is a degree of accuracy by no means easy to attain in practice. The spirit is agitated with chloroform, which increases in bulk, not simply in accordance with the amount of fusel oil it extracts from the spirit, but to a larger extent depending on the quality of the chloroform and other circumstances. The process is doubtless of use for the examination of crude spirits containing a notable proportion of impurities, but fails just at the point where it might give interesting results in the case of whisky and allied products. It is official in Switzerland, where its indications would lead to the condemnation of most pot-still whisky, even that of the finest quality, as having too large a proportion of matters extractable by chloroform.

Another physical method is based on the observation of the height to which the properly diluted spirit ascends a capillary tube.† I have been at some trouble to try this process without much success. The methods which seem really best for the determination of fusel oil are those based on the determination of the contained amylic alcohol, which can be effected with tolerable accuracy, if proper precautions be taken, by oxidising it to valeric acid and estimating the valeric acid formed. Substantially the process is based upon E. T. Chapman's well-known method of limited oxidation by chromic acid mixture. This oxidises amylic alcohol to valeric acid, butylic alcohol to butyric acid, and so on. The acids produced can be determined by ascertaining their neutralising power, or by converting them into and weighing their barium salts. A combination of the two methods enables the mean combining weight of the acids produced by the oxidation to be ascertained, and therefore an estimate to be formed of the proportion the amylic alcohol bears to the other constituents of the fusel oil. A process based on this principle appears to have been first applied to the purpose by Dupré, but his method of working has been greatly improved by Marquardt, who shakes the diluted alcohol with chloroform and then separates the chloroform and subjects that to the oxidation with chromic acid mixture under pressure. When the oxidation is complete the chloroform and aqueous liquid are distilled off and the distillate boiled with excess of carbonate of barium, the liquid filtered, evaporated, and the valerate of barium weighed. In practice, this process presents several inconveniences and sources of error. In the first place it is exceedingly difficult to obtain or purify chloroform so that it will not yield sufficient hydrochloric acid on oxidation to interfere with the estimation unless the mineral acid is estimated and allowed for. I have greatly improved the Marquardt process by substituting tetrachloride of carbon for the chloroform. This solvent has the advantage of boiling at a higher temperature, and hence obviating the necessity of oxidising under pressure, and is obtainable in a state of such purity

* There is good reason to believe that the higher alcohols are chiefly products of a secondary fermentation which is in advance while the chief ferment is active, but proceeds with vigour during the last stages of the process.

† Trumble's stadiometer as improved by Elsworth (Jour. Chem. Soc. 53, 1021).

CHIEF CONSTITUENTS OF WHISKY AND FUSEL OIL.

Empirical Formula.	Name.	Constitutional Formula.	Specific Gravity.	Boiling Point.	Action of H_2SO_4 on Dilute Alcoholic Solution.	Products of Treatment with Caustic Alkali.	Products of Oxidation with Dilute Chromic Acid Mixture.
C_2H_5O	Ethyl alcohol	CH_3CH_2OH	$\frac{15.5^\circ}{15.5} = .7984$ 78.4	Not affected	Not affected	Acetic acid.	Acetic acid.
C_3H_8O	Normal propyl alcohol	$CH_3CH_2CH_2OH$	$\frac{0^\circ}{4^\circ} = .8198$ 98	Not affected	Not affected	Propionic acid.	Propionic acid.
	Iso-propyl alcohol	$(CH_3)_2CH_2OH$	$\frac{15^\circ}{4^\circ} = .791$ 83-81	Not affected	Not affected	Acetone; then acetic and carbonic acids.	Acetone; then acetic and carbonic acids.
	ac-normal butyl alcohol	$CH_3CH_2CH_2CH_2OH$	$\frac{20^\circ}{4^\circ} = .8066$ 117	Not affected	Not affected	Normal butyric acid.	Normal butyric acid.
$C_4H_{10}O$	iso-primary butyl alcohol	$(CH_3)_2CHCH_2OH$	$\frac{20^\circ}{4^\circ} = .8062$ 108-109	Strong coloration.	Strong coloration.	Isobutyric acid; then acetic and carbonic acids.	Isobutyric acid; then acetic and carbonic acids.
	Tertiary butyl alcohol	$(CH_3)_3COH$	Melts at 25°	Not affected	Acetic and carbonic acids.
	ac-normal primary amyl alcohol	$CH_3CH_2CH_2CH_2CH_2OH$	$\frac{0^\circ}{0^\circ} = .8282$ 137-138	Normal valeric or pantoic acid.	Normal valeric or pantoic acid.
$C_5H_{12}O$	iso-primary amyl alcohol	$(CH_3)_2CHCH_2CH_2OH$	$\frac{0^\circ}{4^\circ} = .8238$ 131.4	Coloration	Coloration	Isovaleric or pantoic acid (inactive).	Isovaleric or pantoic acid (inactive).
	gamma-primary amyl alcohol	$(CH_3)(CH_2)_3CH_2OH$	$\frac{0^\circ}{4^\circ} = .805$ 128	Dehydro-acetic valeric acid.	Dehydro-acetic valeric acid.
	Methyl-propyl carbinol	$CH_3CH(CH_3)CH_2OH$	$\frac{0^\circ}{4^\circ} = .8263$ 119-120	Methyl-propyl ketone; then acetic and propionic acids.	Methyl-propyl ketone; then acetic and propionic acids.
$C_6H_{14}O$	Iso primary hexyl alcohol	$(CH_3)_2CHCH_2CH_2CH_2OH$	$\frac{0^\circ}{4^\circ} = .8265$ 152-153	Strong coloration	Strong coloration	Isocaproic acid.	Isocaproic acid.
$C_7H_{16}O$	Iso-primary heptyl alcohol	$(CH_3)_2CHCH_2CH_2CH_2CH_2OH$	103-105	Strong coloration
$C_2H_4O_2$	Acetic acid	CH_3COOH	$\frac{16^\circ}{4^\circ} = 1.0543$ 118	Not affected	Acetate	Unchanged (acetic acid).	Unchanged (acetic acid).
$C_4H_8O_2$	Ethyl acetate	$C_2H_5CO_2C_2H_5$	$\frac{0^\circ}{4^\circ} = .9105$ 74.3	Not affected	Acetate and alcohol	Acetic acid.	Acetic acid.
$C_6H_{12}O_2$	Ethyl valerate	$C_2H_5CO_2C_4H_9$	$\frac{18^\circ}{4^\circ} = .866$ 134.5	Not affected	Valerate and alcohol	Acetic and valeric acids.	Acetic and valeric acids.
$C_8H_{16}O_2$	Amyl acetate	$C_5H_{11}CO_2C_2H_5$	$\frac{0^\circ}{4^\circ} = .8807$ 137	Coloration	Acetate and amyl alcohol ..	Valeric and acetic acids.	Valeric and acetic acids.
$C_{10}H_{20}O_2$	Amyl valerate	$C_5H_{11}CO_2C_5H_{11}$	$\frac{0^\circ}{4^\circ} = .876$ 188	Coloration	Valerate and amyl alcohol ..	Valeric acid.	Valeric acid.
$C_8H_{16}O$	Aldehyde	$CH_3COCH_2CH_2CH_2CH_2CH_2CH_2CH_2$	$\frac{20^\circ}{4^\circ} = .7799$ 21-22	Coloration	Resin, acetate, and alcohol ..	Acetic acid.	Acetic acid.
$C_8H_{16}O$	Acetone	CH_3COCH_3	$\frac{18^\circ}{4^\circ} = .8110$ 56.5	Not affected	Not readily affected	Acetic and carbonic acids.	Acetic and carbonic acids.
$C_8H_{16}O_2$	Acetal (diethylaldehyde) ..	$CH_3CH(O_2C_2H_5)_2$	$\frac{15^\circ}{15} = .8319$ 104-106	Forms alcohol and aldehyde.	Not affected	Acetic acid.	Acetic acid.
$C_8H_8O_2$	Furfural (furfuraldehyde) ..	$C_4H_3O_2COH$	$\frac{33.5^\circ}{2^\circ} = 1.1654$ 161	Strongly blackened	Pyromuric, furfural alcohol, and resinous products.	Pyromuric acid, $C_8H_8O_2COH$.	Pyromuric acid, $C_8H_8O_2COH$.
C_8H_8N	Pyridine	C_8H_8N	$\frac{0^\circ}{0^\circ} = .9858$ 116-7	Forms pyridine sulphate.	Not affected	Not affected.	Not affected.

as to yield no mineral acid whatever on oxidation. The distillate can be titrated with standard baryta water, and the process therefore much shortened; while, if desired, the solution of valerate of barium can be evaporated and the salt weighed, from which can be deduced the combining weight of the acids. Working on pure amyllic alcohol, the product obtained has very closely the combining weight of valeric acid, and the same is approximately true of fusel oil from which any ethylic alcohol has been removed by washing with water. There are some precautions which must be taken with the process to ensure accurate results, among which must be mentioned the use of chloride of sodium or other salt to ensure complete extraction of the amyllic alcohol from the dilute spirituous liquid; but the details of the process I reserve for a future occasion. The oxidation method of estimating amyllic alcohol gives results which are affected more or less by other foreign bodies. Alcohols do not materially affect the results, as they yield acids which are ultimately expressed in terms of valeric acid, and even the isomers which are converted by chromic acid mixture into products other than the corresponding primary acids do not cause such error as might be expected. Thus, for instance, isobutyl alcohol is oxidised first to isobutyric acid and subsequently to acetic and carbonic acids, but the acetic acid produced is exactly equivalent to the isobutyric acid from which it is derived, and hence by titrating the products of oxidation a correct result is obtained. Amylic acetate, on the other hand, will cause error by conversion into valeric and acetic acids, and hence will combine with twice as much baryta as the amyllic radicle of the original ethereal salt. Again valerate of ethyl will show apparent valeric acid equal to twice the quantity really produced.

If the oxidation process of determining amyllic alcohol be applied directly to a spirituous liquid containing ethereal salts, aldehyde, and furfural, the apparent fusel oil will be gravely above the truth, for the acetate and valerate of ethyl will pass into the chloroform, and be subsequently estimated as undesirable fusel oil; whereby most erroneous conclusions may be arrived at. Furfural will also vitiate the results. It follows that to obtain accurate results the spirit should, after distilling it to remove extractive matter, be boiled with alkali to saponify the ethereal salts and decompose the aldehyde and furfural, and the distillate from this treatment extracted with chloroform or chloride of carbon before oxidation. Notably different results are obtained on the same samples of whisky when this modified process is adopted. I pointed out the necessity of the removal of ethers last summer when reviewing the evidence given by Dr. James Bell before the House of Commons on British and Foreign Spirits. It is probable that it is in great measure the omission of this precaution which has caused Dr. Bell to assert that the proportion of amyllic alcohol in matured spirits is somewhat greater than in new. This anomalous conclusion is so opposed to chemical expectation and common experience that it is important to know that the methods of analysis on which it was based are open to exception. Besides oxidising in presence of the ethers and furfural contained in the spirit, Dr. Bell used acid permanganate instead of chromic acid mixture. This alteration in Marquardt's process seems to me open to grave objection on several grounds, but I prefer to ascertain more fully how far the objections are well founded before discussing the matter further.

Among other constituents of ordinary spirits must be mentioned *aldehyde*, which may be supposed to result from the oxidation of ordinary alcohol. I am unable, however, to find that the process of ageing in casks affects very materially the proportion of aldehyde which we should suppose would be among the first constituents to oxidise. It seems probable that it is converted into acetic acid, and that this then forms acetate of ethyl. At any rate the aldehyde does not increase during the process of ageing, and the proportion of acetic and other acids in either new or matured whisky is very insignificant, amounting only to two or three grains per gallon.

There is one constituent of whisky apparently always present in the pot-still product, but absent from spirit manufactured with the patent still. This is *furfural*, which

can be detected with great facility, both in new and old spirit, by its reaction with a solution of aniline in glacial acetic acid, which produces a fine red colour. This reaction is much more delicate than that with strong sulphuric acid, which test is adopted by some chemists. In fact, the reaction with aniline acetate appears to be absolutely peculiar to furfural, and enables it to be detected and the proportion roughly ascertained with great facility. The furfural doubtless owes its origin, together with other pyrogenous products, to the action of the open fire on the contents of the still during the first distillation of the wash. There is more or less suspended matter always present in the wash, and, in fact, a mechanical stirrer is always kept in motion to prevent charring, which, however, is never entirely obviated, and hence the product of the pot-still contains furfural and other products of the action of heat on cellulose and proteids.* Distinct traces of pyridine, collidine, and probably other bases have been found in spirits, and doubtless owe their origin to the same cause. The peat over which the malt is dried also contributes to the flavour of the whisky, and it is probable that a careful search would result in the detection of a distinct trace of phenoloid bodies. It should be borne in mind that addition of water causes a turbidity, due to the separation of oily globules, not only in the feints or last portions of spirit distilled, in which the furfural and fusel oil become concentrated, but also in the foreshots, from which these products are presumably absent. I do not say they are absent altogether, for at the end of a period the head and worm of the still must necessarily retain more or less feints rich in fusel oil, and at the commencement of the next distillation these will pass over into the foreshots or first spirit distilled. So far very little is known of the actual composition of the oily matter precipitated from the foreshots on addition of water. We may expect it to contain the essential oil from the grain, and, not improbably, fatty acids produced from the fixed oil. Where soap is employed the composition will be further complicated. A partial examination of a sample of foreshot oil extracted by Mr. Ross, of Teaninich, showed that a considerable portion could be distilled, while the remaining part consisted largely of fatty acids which could be saponified by treatment with alkali. No soap was used in this still. The distilled portion was examined in my laboratory, and found to have a specific gravity of $\cdot 896$; the free acid, in terms of oleic acid, was 23 per cent.; the unsaponifiable matter, 6.4; and there were also sensible quantities of ethers present. The liquid had a most intolerable odour, quite distinct from that of fusel oil.

I may say that the exact cause of the improvement in whisky, by maturing in casks, is by no means clearly made out. It is usually ascribed to oxidation and the formation of ethers. I have obtained some interesting evidence on these points, but prefer to reserve any comments for a future occasion. As to the question of the change in the proportion of amyllic alcohol by ageing, I have certainly demonstrated, to my own satisfaction, that oxidation does occur, but I doubt if the improvement in flavour is due so much to that cause as to the change in more undefined constituents. One thing seems to be quite certain, and that is that the proportion of amyllic alcohol, and even fusel oil in the widest sense, present in whisky, either new or old, is very trifling, and it is difficult to understand that it is capable of producing the injurious physiological effects attributed to it.

Up to June last a few results by Dupré, and one by Cameron, were apparently the only published figures showing the proportion of fusel oil in *whisky*. Chemists and others have been very ready to talk of "fusel oil" as

* Lindet (Compt. Rend. 111, 236; and this Journal, 9, 1155) has shown whenever the distillation of the spirit has been conducted over a naked fire, as in a pot-still, or whenever the wort has been treated with acid, furfural is present in the distillate, the proportion in the former case ranging from 0.02 to 0.04 cc. per litre, and in the latter from 0.06 to 0.10 cc. A small quantity of furfural (0.01 cc. per litre) was found when the conversion of the starch was effected by diastase, its production in this case being attributable to a preliminary lactic fermentation and the lactic acid acting in a similar manner to, though to a less extent than, the mineral acids. Spirit distilled by steam instead of over an open fire is free from furfural unless produced by one of the above causes.

if its presence in considerable proportions in spirits was an ascertained fact, but scarcely anyone has taken the trouble to ascertain the amount. The following table shows the only estimations published up to the present time pretending to show the proportion of fusel oil in whisky. There are plenty of determinations in brandy, potato-spirit, and other foreign products, but whisky has apparently been left severely alone.

APPARENT AMYLIC ALCOHOL IN WHISKY.

It cannot be too clearly understood that the figures in the table represent the *apparent* fusel oil without the separation of the ethers and other interfering bodies, and not the actual true amylie alcohol, which would be materially lower.

I believe all the results by Dr. Bell and myself are gravely in excess of the truth, owing to the spirit not having been previously treated with alkali, which is a precaution I have taken in all my more recent experiments.

In this connexion I may mention that furfural appears to undergo, by the action of dilute alkali, almost quantitative saponification, with formation of furfuryl alcohol, and pyromucic acid. *Acetal*, which is also a constituent of spirits, is not affected by dilute alkali, but is immediately decomposed by acids into aldehyde and alcohol. I have not been able to find any delicate test for its presence.

With regard to the sample described in the table as "disputed," I may mention that in 1889 a certain firm of Irish distillers supplied a cask of whisky to a customer. When the whisky was finished, the customer declined to pay for it, alleging that it had made him ill; and when sued brought a counter-action for damage to health owing to being supplied with whisky containing a "large percentage" of fusel oil. The case went into court, and I analysed the whisky at the request of the distillers. I obtained only .07 per cent. of fusel oil. A chemist employed by the purchaser found 0.22 per cent. But we know that chemists, no less than judges, lawyers, and doctors, sometimes disagree; and so the judge, at my suggestion, instructed us to make a joint analysis, the result of which was that we agreed that .07 per cent. was the correct figure.

My subject has gone beyond bounds. I have been at work on it for some months, and have a number of figures which I should have liked to have brought forward, but that they relate to a class of facts upon which I am bound to preserve silence until a future occasion. I may, however, in conclusion, direct your attention to a sample of whisky which I have here, and in which I am personally interested. It is a sample of some whisky which I have been taking every evening when at home for some time past, with a view of ascertaining whether it did me any harm. It contains 2 per cent. of added fusel oil, and yet I have not had even a headache through taking it. My friends say that that is because I have not taken enough of it. It is extremely nauseous, but it leaves no doubt in my mind that the effects of amyl alcohol, or whatever other substances there may be in fusel oil, have been absurdly exaggerated. I believe that the whole theory was trumped up by some alchemist about the year 1, and yet people have gone on making these statements while there was not a single figure or accurately observed fact to support them.

I have no doubt the amyl alcohol and other subsidiary constituents of spirituous liquids are of great importance with respect to the flavour and bouquet, but I have grave doubts of their physiological importance. It is worth remembering that taking the whole oxidisable substances present in whisky and calling them amyl alcohol, there is not more than one-tenth per cent., or say a drop in a wine glass, and hence any local effects, such as have been attributed to fusel oil, are more probably due to the ordinary alcohol than the minute quantity of amyl alcohol contained in it, whatever may be the case as to the effect on the system.

I am indebted to Mr. James Greenlees for the loan of the model and the diagrams which are before you, and to Mr. Wm. Chattaway, Dr. A. Colefax, and Mr. Chas. Harrison for extremely able and zealous assistance during the nine months we have been at work on this subject.

DISCUSSION.

The CHAIRMAN said that the points raised by Mr. Allen were certainly contrary to the opinions generally held, and would, he thought, require confirmation.

Mr. J. A. WANKLYN said that for the last 15 or 20 years he had been of opinion that amyl alcohol had nothing to do with the injurious effects produced by whisky. He had long been of opinion that such effects were due to some exceedingly powerful essential oils; and he was pleased to find from Mr. Allen's paper that the subject had been investigated from that point of view, and that the opinion which he had held was now authoritatively confirmed.

Mr. W. COMEN SAMUEL was glad to be able to corroborate the results of Mr. Allen's experiments, more especially with regard to the effects of fusel oil. He also had experimented by drinking for a month past spirits to which had been added various percentages of fusel oil, and had found no ill effects to result, except the nausea referred to by Mr. Allen.

Mr. C. F. CROSS said that some investigations of his into the composition of the by-product known as "pot-ale" having been alluded to by Mr. Allen, he would take the opportunity of calling attention to it in reference to its most characteristic constituent, lactic acid. There were present in addition peptones, carbohydrates, and such inorganic constituents as potash and phosphoric acid; and the solution would appear, "on paper," to be susceptible of a further lactic fermentation. All attempts, however, to bring about such a result had failed.

He now had information from America of the establishment on the large scale of the manufacture of lactic acid by the fermentation of glucose. Mr. Waite, of Boston, informed him that he was able so to control the lactic fermentation that not more than 2 per cent. of the total acidity of the fermented liquors was due to other acids, and that he was producing a 33 per cent. acid at a cost of 2d. per pound. He (Mr. Cross) had suggested that "pot-ale" and similar by-products containing the necessary nutrient materials, in addition to a certain percentage of

lactic acid, might be available in such a process, requiring only the addition of the glucose, and Mr. Waite was carrying out experiments in the direction of so utilising them.

There was no doubt a great field open for a lactic acid industry, its limited use hitherto having depended upon its limited production. As a substitute for acetic acid (and vinegar) in several of its applications, it would come largely into use, and it was already consumed in quantity in the States as a substitute for tartar in wool-dyeing. (See *Textile Record*, August—September 1890.)

Mr. A. P. HOSKISS said that, assuming Mr. Allen's results to be correct, as he had no doubt they were, there was one point of very great interest to him, viz. that in the foreshots of the whisky no amyl alcohol was found. He had had in his custody for some time past a small quantity of a distillate, which he had not yet investigated chemically, but which corresponded to "foreshots" whisky. It was distilled not from whisky, but was the first running from distilled vinegar. It was old, and had been kept in a bottle, and judging by the smell it contained among other things amyl acetate and amyl alcohol. Why the amyl alcohol had come over so early he could not explain, but hoped to be able to do so shortly.

Mr. GREENLEES, referring to Mr. Cross' remarks respecting the utilisation of a "pot-ale," said that in the district of Campbeltown in Scotland, where there were 22 distilleries, "pot-ale" was largely used as a fertiliser. It was pumped up to the top of a hill, from whence it was allowed to run through furrows to the fields below; and its fertilising properties were so great as to add from 10s. to 20s. per acre to the value of the land on which it was used.

Dr. W. S. SQUIRE said that in the manufacture of whisky in Great Britain there was practically no attempt at purification. As Mr. Allen had pointed out, in the manufacture of "pot-still" whisky no such thing was known as fusel oil. The first portions which came over, and which were nasty in flavour, went back again into the next distillation, and practically came into the better part of the whisky, since they never left the process. The manufacture of "pot-still" whisky was, therefore, simply the separation of water from the fermented wash, and the spirit did not profess to be rectified in any way, though no doubt some of the fusel oil was left in the spent wash. In the case of the Coffey still one would imagine at first blush that a considerable rectification of the spirit would occur, but it was chiefly rectified from the water point of view. [Dr. Squire here gave an illustration of the Coffey still, and of the method of carrying on the distillation therein.] So far, he said, from any rectification being effected in the patent still, nothing was taken out but water and fusel oil, all the more volatile bodies going back into the distillation. Patent still whisky was therefore far from being a pure substance. Fusel oil was by no means the only impurity it contained. Some time ago a sample of whisky of 1,000 litres was examined. It produced 997·968 litres of pure spirit, leaving a total impurity of two parts per thousand. (For the composition of this small proportion of impurities, see note, next page.)

The quantity of fusel oil was therefore comparatively small; in fact, not one-third of the total impurities. He might mention that the separation of these bodies presented great difficulty. In the presence of water they were far from distilling in the order of the boiling points of the pure bodies, and it was therefore necessary to eliminate all the water before beginning to fractionate. The question thus arose as to what was the actual change that occurred in the maturing of spirits, if they were so impure as they came from the still. The nature of that change was still somewhat obscure. That the spirit improved if kept in wood was undoubted; that it did not improve in glass was equally undoubted. But that a process of oxidation went on was, he thought, doubtful; at any rate he had never seen any strong evidence in favour of it. Assuming acids to be present, no doubt a certain amount of etherification occurred, but probably the only constituent which would oxidise under such circumstances would be aldehyde, and from its great volatility that would be the first body to

escape by evaporation and be got out of the way. But there was a loss of weight, which was occasioned, he thought, by the more volatile constituents escaping and being volatilised through the pores of the cask, the less volatile constituents being left behind. By determining the fusel oil not directly on the original alcohol, but by first fractionating in considerable quantities so as to eliminate many of the other constituents, the results of his experience accorded with those of Dr. Bell, viz., that the oil did not diminish in the process of maturing, but that the other bodies disappeared to a large extent. He was of opinion, therefore, that the change which occurred was due in great measure to the evaporation of the more volatile constituents of the spirit. Another cause of improvement by ageing was the storing of the whisky in sherry casks, as was shown by the fact that if a sherry cask had been so used once and came back to be filled again, the second lot of whisky did not improve in the same degree as the first; while if new casks were used the improvement was still less. While, therefore, he could not give anything like a clear explanation of the cause of the maturing of whisky, he felt no doubt that, in the case of the Coffey still, if the more volatile products which came from the top of the still were not returned into the distillation, the maturing of the spirit would take much less time than it did at present. But distillers were extremely conservative people, and objected to all change. So difficult was it to get them to introduce any changes that in the case of a large Dublin distillery where a man was killed by the breaking of a crane rope which was used for the purpose of hauling up the grain, the distiller objected to adopt the recommendation of the jury that a chain should be used, on the ground that any alteration in the method of working would spoil his whisky.

Mr. PETER MACLEWAN, referring to Dr. Squire's statement that he agreed with Dr. Bell that fusel oil did not diminish in whisky during the process of ageing, wished to remind the meeting that Dr. Bell had expressly stated that what he regarded as "fusel oil" was not the so-called amylic alcohol, but the total amount of oxidisable matter in the whisky. The figures, which Mr. Allen had quoted, were, he understood, intended to represent the whole of the oxidisable matter that Dr. Bell had been able to extract expressed in terms of "fusel oil" or amylic alcohol. There was a great difference between Dr. Bell's results and those obtained by Mr. Allen. In the latter actual amylic alcohol had been extracted, oxidised, the amount determined as valeric acid, and expressed in terms of amylic alcohol. It was important to keep that in mind, because everything that had been said that evening pointed to the fact that the "quality" was not to be referred entirely to the small amount of amylic alcohol present, but to those other bodies which were undoubtedly also present. He also reminded the meeting that at the Paris Exhibition a complete series of the constituents of ordinary rectified spirit was shown, evidently based upon the analysis mentioned by Dr. Squire.* Every product was definitely named, as a reference to the periodical literature of the time would show.

* The exhibit referred to was the property of M. Eugene Parion, and it was intended to show that by fractionation *Alcohol Brat* (that is dehydrated spirit before final purification) had the following composition per 1,000 litres:—

	cc.
Alcohol (C_2H_5O)	997.968
Aldehyde (C_2H_4O)	110
Acetone	5
Acetic ether	60
A body of sp. gr. '872 and boiling point 73°-76° C.	10
Propyl alcohol	345
A body of sp. gr. '809 and boiling point 101°-102° C.	250
A body of sp. gr. '808 and boiling point 109° C.	430
Amylic alcohol	582
	1,792
Other products	0.249
	1,000.000

(See *Chemist and Druggist*, October 5, 1889.)

Mr. OTTO HEHNER wished to ask the author one question in order to bring out the degree of accuracy which his estimations of the amounts of fusel oil could claim. Had the author ever made any synthetic experiments by adding to pure spirit known quantities of higher alcohols and ascertaining how much he could get back again? If in such test experiments the total quantity added could be accurately determined by the methods adopted by Mr. Allen, considerable confidence could be placed upon the figures obtained by the analysis of actual trade samples.

Dr. S. RIDEAL, in estimating fusel oil in spirits by the Rose-Herzfeld method, had found chloroform a most misleading body to work with, and would be glad to know therefore whether the author considered that it would be practicable to use tetrachloride of carbon instead of it. He would like to know also whether Mr. Allen had noticed any variation in the amount of fusel oil in whiskies of different districts. German investigators had come to the conclusion that the spirit produced in Saxony contained a greater quantity of fusel oil than that manufactured in other localities, and it would be interesting to ascertain whether that was due to the different quality of the malt used, or to the particular breed of yeast employed. He did not know whether any attempts had been made in this country or elsewhere to use pure yeast cultivations in the manufacture of whisky, as in the case of beer. But it seemed to him at least possible that the fusel oil difficulty might be overcome by using a pure yeast which would not produce fusel oil.

Mr. F. H. PERRY COSTE wished to mention a fact bearing upon Dr. Rideal's remarks, which bid fair to become a factor of great importance in the manufacture of alcoholic drinks. The author had referred to the fact that whisky of a different flavour was produced according as one employed a grape yeast or a beer yeast. A great deal of work had recently been done in that direction on the Continent, the result of which was to show that if the grape skins were sterilised so as to destroy the common organisms, and were then inoculated with a growth from the grapes used for the manufacture of special highly-flavoured wines, the effect was that the bouquet and flavour of the commoner wine were indistinguishable from those of the high-priced wines made from the special grapes. It would therefore appear that less importance attached to the material from which the beverage was made than to the cultivation of those special ferments which would impart to it any flavour which might be desired.

Mr. C. E. ASSAL inquired whether the author was prepared, or hoped soon to be prepared, to give some working definitions of brandy, whisky, and other spirits of a more satisfactory character than those at present existing. Public analysts at present worked under considerable difficulties in consequence of the want of clear and sufficiently full definitions in regard to substances of that kind. He thought that he had caught some sort of new definition in the author's remarks in relation to brandy, but it would be most desirable if, as the result of his valuable work on the subject, he could give such extended definitions as would be satisfactory from a legal as well as a scientific point of view. There was a great tendency on the part of those who for various reasons were desirous of dealing severely with the sinning publican, to attack him on the ground that he distributed among a poor population an immense quantity of "poisonous" stuff, and when that common statement was analysed down, it was generally found to mean that he was a distributor of that ill-defined substance, "fusel oil." But it was becoming obvious that the popularly-accepted notions about this substance were erroneous. It might be, as Mr. Wanklyn had said, that there were special substances in spirit which, although in minute amount, might account for the peculiarly injurious effects which were not due to ethylic alcohol. But that also was a loose statement, liable to be misunderstood, and to be used with as little justice and accuracy as the fusel oil theory. He would like to ask Mr. Allen whether he had attempted to separate from any of the spirits with which he had dealt recognisable amounts of a pure amylic alcohol. This, while very difficult, if successfully carried out, was the

only way of obviating the estimation of other substances as amylic alcohol, although it was perhaps hardly worth the trouble.

Mr. ALLEN, in reply, said that he was glad to have been able to make use that evening of a process which originated in part with Mr. Wanklyn, namely, the process of limited oxidation. He and Mr. Chapman were the first to work on the oxidation of ethers, and they now therefore had got a new application of that method which had for so long a time assisted their investigations. He was very glad to find that Mr. Samuel could confirm his opinion as to the innocuous character of fusel oil. It was far more probable that it was the whisky itself rather than the minute proportion of fusel oil which it contained that did the harm. Mr. Cross and himself were concerned some years ago in the investigation of "pot-ale," to which Mr. Cross had referred, and they preserved a lively recollection of the product.

With respect to the vinegar product mentioned by Mr. Hoskins, he would like to know its actual source, for he knew that some so-called "vinegar essence" was sold now which contained 80 per cent. of acetic acid flavoured with acetic ether, and was clearly a factitious product.

Mr. Hoskins said that it was a real malt vinegar.

Mr. ALLEN, continuing, said that with regard to the observations which had fallen from Mr. Greenlees, it might be taken for granted that "pot-ale" contained a sufficient proportion of nitrogenous bodies, peptones, &c., to make its application to the soil beneficial. He believed that Mr. Coffey, jun., was present during Dr. Squire's remarks, and he regretted that they had not had the advantage of a few words from him. The Coffey still was wonderfully scientific, but its action would be more perfect if arrangements were made enabling one to take off the top products, as pointed out by Dr. Squire. They drove the process to an extreme, and therefore volatilised from the wash the whole of the amylic alcohol present; whereas in the "pot-still" the wash was never entirely exhausted of alcohol. Moreover, in the latter case, the process was conducted far more slowly, and the conditions being so different, it by no means followed that all the amylic alcohol passed into the whisky, some of it probably being left in the spent lees and pot-ale. Dr. Squire had had the advantage of working on much larger quantities than he had, and the investigations which he had described were extremely interesting, especially the fact that of the total impurities in 1,000 litres of whisky only one-fourth consisted of amylic alcohol. Hence, to oxidise all the extractable bodies together in chloroform solution was a faulty method of working, and one that should be avoided. He might remark that a new process for ascertaining the proportion of amylic alcohol had recently been proposed by Muller. It consisted in keeping back the aldehydes with aniline phosphate and treating the distillate with sulphuric acid, which gave a coloration which was supposed to correspond to the amylic alcohol or other higher alcohols present. He had tried the process and found it useless. Even with a proportion of 0.2 per cent. (which was ten times as much as they might have) the colour was indistinct. He therefore placed no confidence in that process at present. With regard to the statement about propylic alcohol, he was glad that Dr. Squire had isolated that body from whisky. The same thing had also been done in Germany. They were in the habit of thinking of amylic alcohol and butyric alcohol as present in spirits because they made themselves evident in the fusel oil, but the lower homologue was forgotten. Mr. Chapman had found it to be the most difficult of all known substances to dehydrate. A hydrate of propyl alcohol existed, which had practically the same boiling point as ethyl alcohol, and as the last trace of water would stick to the propylic alcohol and reduce its boiling point to that of ethyl alcohol, the separation of the two by fractional distillation was extremely difficult. No wonder, therefore, that one did not isolate it by that method, though conversion of the alcohols into the iodides or bromides, and fractionation of these was more promising. He himself had made some experiments to show the presence of propylic alcohol in spirits by a process suggested by Mr. Helmer, but he had not succeeded

in finding any sensible quantity of propylic alcohol. That brought him to Mr. Helmer's question, as to whether he had verified the accuracy of the oxidation process. He had taken pure amylic alcohol, dissolved it in a large quantity of proof spirit, shaken the diluted liquid with chloroform or tetrachloride of carbon, and had got an amount of valeric acid equal to from 95 to 100 per cent. of the amylic alcohol originally taken. He had therefore no doubt of the accuracy of the process when carefully conducted, but, as already stated, he preferred tetrachloride of carbon to chloroform for several practical reasons. Dr. Rideal's suggestion as to use of chloride of carbon in Rose's process was a most interesting one, and he should like to try its effect. As to the proportion of fusel oil in the whisky produced in different districts he could give no information. The distillers who had been so kind as to supply him with samples would hardly thank him if he stated that their whisky happened to have two or three more grains of amylic alcohol per gallon than others. The question of flavour referred to by the next speaker was certainly interesting; and in connexion with it he might mention that malt-distillers regarded the water they used as an important factor in producing the characteristic flavour of their whisky. With regard to Mr. Cassal's remarks, a Parliamentary Committee was now sitting to decide, among other points relating to spirits, the question of definition. It was however very difficult to formulate an accurate and acceptable definition. He himself had proposed to define whisky as a spirit made from fermented grain (malted or unmalted) in a pot-still. But that definition excluded altogether the product of the patent still; and whether that was desirable remained to be seen. They could distinguish pot-still whisky by means of the furfural test, but how were they to find the patent still whisky or silent spirit? It would be useless to have a definition if they could not make use of it.

Meeting held on Monday, April 6th, 1891.

MR. TYLER IN THE CHAIR.

ON THE VOLUMETRIC ESTIMATION OF ALUMINA.

BY G. LUNGE.

A PAPER bearing the above title has been read at the meeting of the London Section of the Society of Chemical Industry, on February 16th. From the first report which I got of that paper through the "Chemical Trade Journal" of February 28th, I saw that the authors, Messrs. Cross and Bevan, performed titrations before the meeting in order to show that the statements made by me were erroneous. To judge from the discussion as it is reported in the Journal of the Society itself, they seem to have succeeded, one gentleman going as far as to say that "the evidence brought before the meeting was, in his opinion, so conclusive that it admitted of no discussion." Other gentlemen present appear to have suggested as a cause of my erroneous conclusions that I was probably colour-blind, and could not distinguish the colour-change with methyl-orange.

I am sorry I cannot admit any defect as to colour vision, as I am really *not* colour-blind. I have now lectured for 15 years on colouring matters and dyeing, and I am considered a very fair judge of delicate tints. I have for 32 years worked in volumetric analysis, and I honestly believe that my accuracy and that of my co-operators may be regarded as unimpeachable in the working out of new specific gravity tables for sulphuric, hydrochloric, and nitric acid, where we ultimately attained to an accuracy of $\frac{1}{10000}$. Last, not least, the very indicator in question, methyl-orange, has been first introduced into science, and its uses have been worked out by myself. Thousands of

other titrations have been made by myself or under my eyes with that indicator, which owes its very name to me (formerly, when it was used as a dye, it was called by various partly misleading names). There is, thus, no excuse whatever for my blunder I may have committed in that direction on the score of colour-blindness. Moreover, all my assistants and co-operators must have been equally colour-blind, which is not a very likely assumption.

It may be said that Messrs. Cross and Bevan have demonstrated the correctness of their views by performing titrations in the presence of the meeting. But have they really done that? I think not, because actual proof can be afforded only by the most careful following up of the operations in the laboratory, from beginning to end, including the gravimetric determinations. Nobody could have suspected from the outset that Messrs. Cross and Bevan did not obtain a change of colour at some point which seemed to them to prove the correctness of their views; and if they were wrong (as I believe they are), the fault must have been in some constant source of error, overlooked by them, and hence repeated in their titrations before the meeting as well. Where that fault may have been I can only guess, but if that guess, as I shall later on indicate, is wrong, that detracts nothing from the force of my own observations, since it cannot be my duty to point out possible sources of the error to which my critics were liable.

The impurity of some samples of methyl-orange found in commerce was also adduced by some of the speakers as a possible explanation of the discrepancy between our results; but there is really nothing in that. It is true that some of the methyl-orange of commerce is largely adulterated with dextrin or similar matters; but this does not in any way account for the above discrepancies as pointed out by Mr. Cross himself. My own methyl-orange was prepared in my own laboratory, and is a perfectly pure crystalline body; but the rather impure sample sent to me by Messrs. Cross and Bevan gave exactly the same results as my own; it was only necessary to employ a little more of the indicator.

As I was not present at the meeting, Messrs. Cross and Bevan could not be controverted by me, hence, probably, the audience were impressed by their contention. I desire, therefore, to justify the position I have taken now.

The controversy turns upon the point whether, in titrating alumina with methyl-orange a permanent pink shade appears when the ratio: $3 \text{H}_2\text{SO}_4$ to $1 \text{Al}_2\text{O}_3$, or rather, when the ratio: $5 \text{H}_2\text{SO}_4$ to $2 \text{Al}_2\text{O}_3$ is obtained, the latter being the contention of Messrs. Cross and Bevan.

That on titrating solutions of sodium aluminate, the point of saturation is reached when the proportion of $3 \text{H}_2\text{SO}_4$ to $1 \text{Al}_2\text{O}_3$ has been obtained, had been the general opinion before Messrs. Cross and Bevan published their paper. And that opinion was not a mere assumption, but the result of experimental investigation. The above-mentioned ratio has been found for methyl-orange by Mr. R. T. Thomson, whose work on indicators is acknowledged to be of the first order (Chem. News, 47, 135). Exactly the same was found for tropaeoline, OO, by K. J. Bayer, whose paper was mentioned by Messrs. Cross and Bevan themselves in their first publication. They knew that paper only indirectly; had they seen the original (Zeits. f. Anal. Chem. 1885, 542) they would have found that his results accord with the above ratio. So did mine, obtained with methyl-orange, as published in the Zeits. f. angew. Chem. 1890, 227. Moreover, it has been frequently proposed to titrate any free acid present in commercial sulphate of alumina by means of standard alkali and methyl-orange, which would be clearly impossible if the last-mentioned indicator showed a change at the ratio $5 \text{H}_2\text{SO}_4$ to $2 \text{Al}_2\text{O}_3$. I must emphatically insist on the point that before Messrs. Cross and Bevan's paper there had been a *consensus omnium* as to the ratio $3 \text{H}_2\text{SO}_4$: $1 \text{Al}_2\text{O}_3$.

It is true that those gentlemen allege that M. Blondel agreed with them, according to a foot-note in a French journal. But I have already, in private correspondence with them, proved that they are labouring under a mistake in that matter. M. Blondel did nothing but abstract the above-mentioned paper of Bayer's; that he made any

observations of his own, that these observations were made with litmus and methyl-orange, and that they agreed with the ratio 5:2, is simply a gratuitous assumption not warranted by the journal in question. And even if it were true, it would be useless for our controversy, as certainly not a single analysis of Blondel's is quoted anywhere in figures.

As we must dismiss M. Blondel from consideration in our case, we come to the paper by Messrs. Cross and Bevan, published in the Journal of this Society, 1889, 253, in which there is just one line on the estimation of sodium aluminate, and one analysis bearing upon that matter which formed the subject of my short communication mentioned above, in which I overlooked that line and that analysis.

When I became aware of their paper, I at once set about going over the ground again, and, in order to eliminate any personal errors, I caused my demonstrator, Dr. Rey, to do the same without any bias whatever one way or another. Our results have been published in the Zeits. f. angew. Chem. 1890, 293. A solution of pure sodium aluminate was analysed both gravimetrically and volumetrically. By the first method we found 2.820—2.816; that is 2.818 grms. Al_2O_3 per litre. Volumetrically we consumed for 10 cc. solution in eight tests from 10.53 to 10.69, on the average 10.60 cc. of decinormal acid up to the point where phenolphthalein was decolourised, and in 14 tests from 27.10 to 27.7, on the average 27.19 cc. decinormal acid to the point where methyl-orange gave a permanent pinkish tint. Half of the tests were made with standard hydrochloric acid, the other half with standard sulphuric acid, as detailed in the original. Deducting 10.60 from 27.19, we obtain for alumina 16.59 cc. This, multiplied by the factor 0.0017, corresponding to the ratio $3 \text{H}_2\text{SO}_4$: $1 \text{Al}_2\text{O}_3$, yields 2.8203 cc., which agrees very well indeed with the gravimetric figure of 2.818. If we had applied Messrs. Cross and Bevan's factor = 0.00212, we should have obtained the impossible figure 3.517 for the alumina present.*

In the course of our work we found an important fact, subsequently completely confirmed by Professor Treadwell and Mr. Häuptli (see below). We observed that at the ordinary temperature the action of the acid was very slow. The pink colour appeared long before it was due, but it vanished again after a certain time; when more acid was added the same process repeated itself over and over again; but at last a point came when the pink colour remained permanently, and this point was evidently the end of the reaction. Especially when this was near it took sometimes half an hour or more after each addition to make sure whether the colour was permanent or not. As I noticed that this time was greatly lengthened on a day when the laboratory was badly heated, I tried the opposite measure, viz., heating the liquor to about 40° C. (not above this, because methyl-orange acts badly with hotter liquids), and I now found that at that temperature the process, formerly almost useless on account of its being so very tedious, was quite as expeditious as any ordinary titration. We therefore advised working a little above the ordinary temperature; but the final results are identical in both cases, if enough patience is employed.

Probably that is the explanation why Messrs. Cross and Bevan (as well as their co-operators) obtain erroneous results; they work at the ordinary temperature and they do not wait long enough for the pink shade to fade away again, and they are thus led to believe that the point of saturation comes earlier than it does in reality. Whether that is the case, or whether the error they commit is somewhere else, I cannot, of course, say with any degree of certainty.

My paper led to a somewhat extended correspondence between Messrs. Cross and Bevan and myself, and to fresh experiments on my part, which, however, did not bring my own and Dr. Rey's work nearer to that of Messrs. Cross and Bevan.

I will quote our new results (not yet published, but communicated to them). The same solution of sodium

* We employ the atomic weight 27.1, quoted as nearest the truth in Ostwald's standard treatise.

aluminate which we had employed before, was again tested by Dr. Key and myself, both of us checking all readings. But whilst formerly we had been working in the manner published in my former paper, viz., heating the liquid to about 40° C. and titrating it directly with standard acid till the first pinkish shade permanently remained (when working *in the cold*, this would take many hours, whilst at about 40° the titration could be made in a few minutes), we now operated as described by Messrs. Cross and Bevan, viz., adding a slight excess of standard acid and retitrating with caustic soda, both at the ordinary temperature. Our former experience had taught us that we should get entirely wrong results if we retitrated *at once*, and we therefore allowed the acidified liquid to stand for 24 hours before retitrating with caustic soda. The result was the same as before. Whilst the average of our former tests had been 10.60 cc. for phenolphthalein and 27.16 cc. for methyl orange, the new tests required 27.10, 27.10, 27.12, 27.18, that is exactly as before. In a further experiment we purposely retitrated *at once*, as Messrs. Cross and Bevan do, and consumed only 26.68; but this result was evidently wrong, for the alumina precipitated did not dissolve immediately, thus proving the incorrectness of that way of proceeding.

Even this result is far above that which Messrs. Cross and Bevan's theory would have required, viz., 21.37 cc., and I cannot but ascribe their low results to anything but chance errors repeating themselves in about the same manner owing to the same imperfection of manipulation.

A little later we received from Messrs. Cross and Bevan a sample of the methyl-orange used by themselves, and we went once more into the matter. We first repeated the gravimetric estimation, and found exactly as much alumina in our solution as before, viz., in 40 cc. 0.1129 (formerly 0.1128) gm. Al_2O_3 . On titrating 10 cc. of the same solution, 27.16 cc. decinormal acid was used, deducting 10.60 for the acid consumed with phenolphthalein, we have 16.56 for 10 or 66.24 for 40 cc., or, multiplied by 0.0017, 0.1126 Al_2O_3 , exactly as much as by gravimetric analysis, and again confirming our theory. We also made a gravimetric analysis of the soda contained in our solution of sodium aluminate, and found this to agree exactly with the acid consumed in the phenolphthalein test; thus leaving no shade of doubt that the difference between the two titrations referred entirely to alumina, and that the methyl-orange indicated the point when the compound $\text{Al}_2(\text{SO}_4)_3$ had been formed.

Although I was (and am) positively sure that no mistake was possible in Dr. Key's and my work, I could not but admit that any outsiders would accord equal credence to two such able chemists as my honourable antagonists in this controversy. It was clear that a third party would have to be called in as umpire. I therefore submitted the affair to Dr. Treadwell, professor of analytical chemistry and head of the analytical laboratory at the Zurich Polytechnic School, a former pupil of Bunsen's and Victor Meyer's (in company with whom he has published an excellent manual of qualitative analysis). Professor Treadwell has trained many hundreds of chemists in all the subtleties of analysis, and is daily working in that field with fullest assiduity; he is universally acknowledged to be a model of conscientiousness in his work, and I know of no analyst in Europe whose skill and carefulness were superior to his. Professor Treadwell at my request kindly consented to investigate the matter in an entirely independent manner, taking merely the published data into consideration. In order to exclude any chance of error on his part he associated himself with an advanced student of his, Mr. Huppli, who worked under his eyes. Every single weighing was checked by both of them, and the titrations were performed by each of them independently many times over, and absolutely independently of myself. The following is a faithful translation of the report made to me, in which I have merely left out the details of weighings and titrations, not to make the matter too lengthy.

A solution of sodium aluminate was made by dissolving 0.5182 gm. aluminium metal in about 2 grms. pure caustic soda made from sodium. The solution was filtered and diluted to 500 cc. 25 cc. was acidulated with HCl, evaporated to dryness, filtered from the silica, the alumina precipitated

with ammonia and the soda estimated in the filtrate as NaCl. Results of two parallel analyses:—

			Mean.	Per Litre.
SiO_2	0.0005	0.0006	0.00055	0.022
Al_2O_3	0.0474	0.0476	0.0475	1.900
NaCl	0.6136	0.6130	0.6133	24.532
— NaOH				16.796

For the titrations 50 cc. of the above solution was diluted to 200, and 20 cc. (= 5 cc. of the original solution) taken for each test. The titrations were made with sulphuric and hydrochloric acids, both of them very nearly decinormal and exactly standardised, and the temperature was between 20 and 30° C., too much time being consumed when working at a lower temperature.

A.—TITRATIONS WITH SULPHURIC ACID.

	Phenolphthalein.	Methyl-Orange.
	27.10	26.5
	27.10	26.52
	27.10	26.50
Treadwell,	27.10	26.5
	27.10	26.5
	27.10	26.48
	27.10	26.5
Huppli,	27.02	26.48
	27.03	26.49
	27.0	26.5
	27.0	26.51
	27.0	26.50 = 5.50 for Al_2O_3
Corrected,		5.53

1,000 cc. hence contain 16.7577 NaOH.

1.8802 Al_2O_3 (factor 0.0017).

B.—TITRATIONS WITH HYDROCHLORIC ACID.

	Phenolphthalein.	Methyl-Orange.
	20.99	26.50
Treadwell,	20.99	26.46
	20.99	26.40
	20.93	26.42
Huppli,	20.92	26.43
	20.93	26.43
Having for Al_2O_3		5.50

This corresponds to 16.727 NaOH

1.870 Al_2O_3 (factor 0.0017).

General result:—

	Found by Weight.	Titrating with H_2SO_4 .	Titrating with HCl.
NaOH	16.796	16.758	16.727
Al_2O_3	1.900	1.880	1.870

This is altogether confirmatory of the factor 0.0017 used by all previous observers and by myself.

With Cross and Bevan's factor = 0.00212 the impossible figure 2.344 for Al_2O_3 would have come out.

Since in Treadwell and Hauptli's experiments the *soda* as well as the *alumina* were estimated gravimetrically, and since this estimation, as proved by the above figures, entirely agrees with the titration, it is impossible to assume any error in their volumetrical estimation of the *soda* which would have influenced that of the *alumina*. Their analyses therefore confirm the results of all previous observers, according to which the change in the colour of methyl-orange occurs when 3 H_2SO_4 has been used for 1 Al_2O_3 , and they are a conclusive refutation of those of Messrs. Cross and Bevan.

I cannot imagine any other means for arriving at the truth; I believe that far more than sufficient evidence has now been collected in refutation of the conclusions of Messrs. Cross and Bevan, and I shall, therefore, not continue the controversy. If anybody still believes in the ratio of 5:2, I shall at any rate have done my part in preventing what I believe to be a wrong "fact" to creep into chemical literature.

At the conclusion of their paper Messrs. Cross and Bevan take exception to my statement that the silicate and aluminate present in commercial caustic soda "in well-nigh all practical cases acts like the hydrate."

This statement, they observe, practically amounts to saying that soda which is already combined with an acid is as capable of combining with other acids or bodies of an acid nature as the pure hydrate, and "this will indeed be news to the soap-maker and paper-maker." I for my part think better of the soap-maker and paper-maker than assuming, as my honourable opponents do, that perfectly well-known facts referring to his trade are indeed "news" to him. He *does* know that the term "available alkali" has *always* included the silicate and aluminate; he *does* know that the "acids" combined with soda in those compounds, viz., silica and alumina, are weaker than the weakest of ordinary acids, that is carbonic acid; he *does* know that, in consequence of this, silicate of soda approaches to and sometimes exceeds caustic soda in its action on fatty matters and other "scouring" properties, and that aluminate of soda is actually sold to soap-makers, who want to "fill" the soap with alumina, because the soda combined therewith will saponify their fats like the hydrate; he *does* know altogether that for all practical intents and purposes the fractions of a per cent. of silica and alumina present in commercial caustic do not in the least interfere with the use of the soda itself. Or if he is really ignorant of the above, he is not a very learned member of his trade, and he ought to know better. I am content to leave the judgment to third parties. *Minima non curat prator*, and the silica and alumina in caustic soda are "*minima*."

DISCUSSION.

Mr. E. J. BEVAN said that it was not his intention to trouble the meeting at any great length. The matter at issue between themselves and Dr. Lunge had been more or less thrashed out in the various papers that had been read; and if any one who was interested in the subject, and had occasion to perform such an analysis as the estimation of alumina in presence of caustic soda, would be good enough to bear in mind the conflict of opinion that existed, they might try the experiment for themselves and see who was right and who wrong. That would amply satisfy himself and his colleague. With regard to Dr. Lunge's suggestion that there was something wrong with the methyl-orange, that, as had already been pointed out, could not be the case; for samples of the reagent had been exchanged, without any effect on the results obtained by themselves and Dr. Lunge respectively. It was only fair to point out, as Mr. Mumford had not mentioned it, that some of Dr. Lunge's results had been obtained at a higher temperature than that which

Cross and Bevan employed. It was not relevant to the question to bring forward numbers obtained in that way, as it constituted an essentially different process. With regard to bringing in third parties to investigate the matter, they had got several third parties to make the examination. One of them was their own laboratory assistant, who had never performed such an operation before. They gave him the solution to titrate with phenolphthalein and methyl-orange, merely instructing him to add excess of acid and then titrate back again. They had similarly got Dr. Evans to confirm their results. It seemed absolutely impossible that independent observers should deliberately and wilfully hit upon such an extraordinary reaction as the one they had obtained if it had no foundation in fact. As he had said, the observation made by Prof. Lunge at a higher temperature, was irrelevant, but he might add that he had tried the experiment at the higher temperature and had got results similar to those obtained at the lower temperature. Still, in his opinion, Dr. Lunge should not have brought forward such numbers, because they might have given altogether different results. He would now leave those who were interested in the matter to read the various papers and decide who was in the right.

The CHAIRMAN said that it appeared to be a repetition of the old story of observers differing simply because the conditions differed. After all was not "temperature" at the bottom of this? When Prof. Lunge next visited England, he hoped that he would pay a visit to Messrs. Cross and Bevan's laboratory, and discuss the matter with them and a mutual scientific friend. The result could then be notified to the Society through the Section.

NOTE BY DR. LUNGE.

Having received a proof of my paper, together with the discussion, I beg to point out that the higher temperature employed in some of my and Professor Treadwell's titrations does *not* make any difference in our contention. The results obtained at 30° to 40° are *identical* with those obtained at 15° C., but in the second case it is necessary to wait a long time before the colour changes are definitely pronounced, and the error may lie there.

ERRATA.

March number of this Journal, page 205, col. 1, line 14, for "silver, nitrate" read "silver nitrate."

Page 206, col. 1, par. 3, line 1, for "experimentants" read "experiments."

Col. 2, Mr. Veley's second paper, par. 2, line 5 of that paragraph, for "pyrometer" read "pycnometer."

Ibid, footnote, for "hydroxybenzoic acid" read "hydroxybenzoic acids."

The following have been elected to fill the vacancies and will take office in July next:—*Chairman: H. Bannister; Vice-Chairman: A. Norman Tate; Committee: E. Carey, V. C. Driffield, and F. Hurter.*

Meeting held on Wednesday, April 1st, 1891.

MR. A. NORMAN TATE IN THE CHAIR.

THE SECTOR AND GREASE-SPOT PHOTOMETERS.

BY F. HURTER, PH.D.

WHILST paying a visit to Liverpool as judge of the Photographic Exhibition, Captain Abney kindly spent a few hours with Mr. Driffield and myself at Widnes. He inspected our instrument for measuring densities, and such other of our experimental work as we have exhibited before this Society. I shortly afterwards took advantage of an opportunity to pay a return visit to Captain Abney at South Kensington, and made some experiments with his own sector photometer. The results of both investigations I hasten to lay before the Society.

With respect to the experiments which Captain Abney made with our photometer at Widnes, they were confined to measurements of the densities of two plates, the mean densities of which were respectively 1.136 and 1.913. Three measurements were made of the first plate, and six of the second. Captain Abney's extreme readings, at as different parts of the scale as possible, differed by 2.57 per cent. in the first plate and by 3.6 per cent. in the second plate, *i.e.*, the instrument gave a mean value ± 1.8 per cent.

We have received a letter from Captain Abney, in which he bestows his unqualified praise upon our instrument, both for its handiness and for the consistency of its readings. In fact, there is only one point about which he now hesitates, and to which I shall presently refer.

The experiments made with the sector at South Kensington showed that, under the conditions as to speed of revolution, distance of screen from sector and lamp, &c., and within those limits between which it was tested, *viz.*, with light intensities ranging from 1 to $\frac{1}{25}$, the sector accurately agreed with the law of inverse square of distance.

Whilst we ourselves used the sector under conditions in which its errors are maxima, *viz.*, with broad flames, and in very close proximity to the lamp and screen, Captain Abney uses the sector under conditions in which we have found that the error is very trifling, *viz.*, with comparatively narrow flames, considerable distances between screen, sector, and lamp, and, more particularly, with a high number of revolutions. Captain Abney's sector has two openings, and makes upwards of 2,000 revolutions per minute, which is equal to a speed of 1,000 revolutions with a single opening, and if

our diagram (this Journal, 10, 21) be referred to, it will be found that for this number of revolutions our own experiments show the sector to be almost accurate, even with broad flames and relatively small distances.

We should be extremely sorry if any of our remarks have in the smallest degree detracted from the value of any of Captain Abney's beautiful researches on colour. He was good enough to show me some of these experiments, and I quite agree with him in saying that the revolving sector is the only instrument which could possibly be used in these particular investigations.

After my experiments with Captain Abney's sector, we have no hesitation whatever in stating that, as he uses it, it is a perfectly trustworthy instrument, and it certainly is, as we always considered it, an extremely beautiful device for rapidly varying the intensity of a given beam of light.

There is no longer, therefore, any difference of opinion between Captain Abney and ourselves as to the correctness of our respective instruments, but the Captain is not yet satisfied that our photometer gives the true optical density. As we ourselves know that it does not, and never held that any one particular number could possibly represent the true density, we shall have no difficulty in arriving at an understanding on this point, and we have pledged our word to settle this one remaining difference experimentally in conjunction with Captain Abney, and without any further controversial publications. We designed our photometer with a view to making it a substitute for chemical analysis, in order that its readings should be proportional to the weight of silver deposited, rather than give the true optical density, which, for the purpose of our research, is so far of secondary importance, and our last paper on the relation between positive and negative clearly shows that the density, however expressed, will need different corrections for different printing operations.

FURTHER EXPERIMENTS ON THE INTRODUCTION OF HOME-GROWN SUGAR.

BY G. SCHACK-SOMMER, PH.D.

WHEN I had the honour of coming before you 12 months ago it was for the purpose of describing the then results of my experiments, made with the object of introducing into this country, and into Ireland, the cultivation of beetroot with the object of sugar manufacture as is at present so largely carried on upon the Continent. From all sides I have received the warmest encouragement to go on with my experiments until they are carried to a practical issue. From all sides, that is to say with one exception, which you will admit has been a sufficiently remarkable one, the farmers of all people in the world, have, as a class, been indifferent or apathetic, though to this rule there have been some honourable exceptions. Generally speaking, however, they appear to have entirely failed to grasp any idea of the possibilities—may, the certainties—of profit opened up by this new branch of agricultural industry. They are content to go on in the old stereotyped ways of their fathers as if the raising of a really profitable new crop was to them a matter of perfect indifference. This may be conservatism or it may be distrust of anything in the nature of experiment, but what is certain is that farmers on the Continent have every reason to be satisfied with a state of things which leaves them without British competition in a profitable industry in the carrying on of which they are much more independent of the kind of weather they have in a season than in the case of ordinary agricultural operations. Under such circumstances it is not, I think, too much to assume that English farmers do not possess the enterprise of their continental rivals, and one surprising evidence of this is supplied by the fact that I have not had an inquiry for seed or for any further particulars from a single farmer in England. From Ireland, on the contrary, I had over 50

applications, and in a lecture I gave in London to members of Parliament on the 12th of last June I was able to say that I had seed in more than 50 farms in about 20 counties in Ireland. This was in consequence of the "Weekly Freeman" having, with my permission, published an extract from my first lecture delivered here, and of an intimation that those who liked to make similar experiments to mine in 1889 could, by applying to me, obtain seed gratuitously.

The names of those who did apply and who got seed from me I forwarded to Messrs. Newlands Brothers, of London, with the very desirable object of having the evidence of an independent chemist with experience in the analysis of beetroot as to the quality of the roots. Messrs. Newlands Brothers sent a circular letter to all these farmers, acquainting them with this fact, yet in one case only they received a consignment of roots which were grown at Ballyteigue Castle, Kilmore Quay, county Wexford, and they sent me the results, which are as follows:—

An average sample taken from these 17 roots gave the following results:—

Specific gravity of juice at 60° F.	1.0745
Decrease by Brix saccharometer	18.92
Quantity of sugar in 100 parts	11.64
Quantity of non-sugar in 100 parts.....	3.58
Including mineral matter.....	1.93
Quotient of purity.....	81.21

Weight of the four roots with leaves:—

	Grms.
Average weight with leaves.....	1155
Without and trimmed	837.5
Weight of the largest with leaves	1410
Weight of the largest without and trimmed	1030
Weight of the smallest with leaves.....	1000
Weight of the smallest without and trimmed	714

Weight of the 13 roots without leaves, and trimmed in grammes:—

490, 540, 620, 680, 780, 840, 850, 870, 900, 930, 1050, 1140, 1220.

Average weight of the whole 17 roots trimmed 839 grms. (about 29 ozs.).

With the one exception of the results above, we received in the majority of cases no answer at all, and when we did, it was to the effect that if we, after supplying the seed gratuitously, would pay for the carriage of the roots to mine or Messrs. Newlands' laboratory, they would forward the required number. The proposal, in fact, was treated as if it was one in which I alone had a pecuniary interest, and as if the last thing in the world to interest farmers was the establishing of a new and profitable agricultural industry, even when others were disposed to go out of their way to take all the preliminary trouble off their hands beyond that of simply allowing the roots to grow on their farms. The British farmer in fact, with the prospects of agriculture at their lowest point of depression, did not seem to possess even that sort of gratitude which has been cynically defined by Rochefoucauld as a lively expectation of favours to come.

The very few exceptions to this rule which I am able to name are the following. Before everybody else I have of course to name Mr. John Gibbons, who with his steward, Mr. McBride, has given me again this year invaluable help and assistance, and so has Mr. John Ennis, of Ballymitty, co. Wexford, Ireland, and the following gentlemen:—

Rathdown Union Workhouse (Mr. Jno. Conway, agriculturist), Loughlinstown, co. Dublin.

Mr. R. P. Gray, Spring Lodge, Athy, co. Kildare, Ireland.

Mr. J. H. McNaught, Modreeny House, Cloughjordan, co. Tipperary, Ireland.

Mr. W. Smith, Dodsbros', Lucan, co. Dublin, Ireland.

Mr. J. Costello, Graigue Lodge, Tuam, co. Galway, Ireland.

Mr. Jas. Watson, Rose Cottage, Portaferry, co. Down, Ireland.

Mr. J. C. Mayler, Harristown, co. Wexford, Ireland.

Mr. Jas. Kehoe, Moortown, co. Wexford, Ireland.

Mr. M. Byrne, Ballyknock, co. Wexford, Ireland.

Miss Richards, Ballymitty, co. Wexford, Ireland.

Mr. F. Keane, Listernan Farm, co. Mayo, Ireland.

Mr. Jno. Jack, steward, Pakenham Hall, Castlepollard, co. Westmeath, Ireland.

Mr. Mark White, Castletown, co. Wexford, Ireland.

Mr. Thomson Aikman, jun., Glasgow.

Mr. H. J. Mirehouse, St. George's Hill, Easton-in-Gordano, Bristol.

Mr. H. Halix, Henley, Surrey.

Mr. A. Dickson, c/o Mr. Morgan Mooney, Rogerson's Quay, Dublin, Ireland.

And I sincerely thank them for the liberal and enterprising spirit in which they have met me. I only hope that it will not be long before they are abundantly recompensed for any trouble or expense they may have been put to by the successful introduction of this beneficial solution of the agricultural problem of how to enable English and Irish farmers to make a living upon their holdings.

As bearing upon this I may remark incidentally that from the very best authorities on the Continent I have gathered the information that the immediate result of opening a beetroot factory in convenient proximity to the growers is to increase the value of land by one-third.

Before giving you the results of the experiments I made last summer permit me to indicate some of the points which have struck me as capable of further elucidation in my previous dealings with this subject. The first point to which I wish to direct your attention is that of the selection of seed, and I have no doubt you have wondered why I have not limited my experiments to one sort of seed. Though, however, you are members of the Liverpool Section of the Society of Chemical Industry, as I am myself, you are not agricultural chemists, and you will be surprised to hear that all the information I have been able to gather puts the technical chemist decidedly in the background so far as the development of the sugar industry on the Continent is concerned. In this the palm of merit must decidedly be given to the agricultural chemist, who, by incredible industry and inexhaustible patience, has managed to bring the saccharine strength of the beetroot as high as that of the best sugar-cane. I call upon you, therefore, my fellow labourers in this Section, to do honour to achievements which claim your admiration, even though you may regret your inability to grasp for yourselves the laurels of victory. As evidence of what has been done in France in the way of developing this cultivation, pray note the fact that while in 1881—82, the yield of sugar per hectare, a little over two acres, was 1 ton 14½ cwt., in 1885—86, it had risen to 2 tons 6½ cwt.; and 1889—90, to 3 tons 1½ cwt., an actual doubling of the production in the short space of 10 years. Pray note, too, that not only has there been an enormous increase in the saccharine strength of the French beetroot, but that this has been accompanied by great improvements in the machinery and manipulative processes of manufacture. For instance, in France in 1881—82, to manufacture one ton of sugar they used 17 tons 3½ cwt. of beetroot; in 1885—86, 11 tons 8½ cwt.; and in 1889—90, 8 tons 11½ cwt. I will give you the figures for each year so that you may more clearly appreciate the rate of progress:—

	Average Quantity of Sugar produced per Hectare.	Average Quantity of Beetroot used to make 1 Ton of Sugar.
	Tons, Cwts.	Tons, Cwts.
1881—2	1 11½	17 3½
1882—3	1 15½	17 17½
1883—4	1 19½	16 5
1884—5	1 17½	15 9½
1885—6	2 6½	11 8½
1886—7	2 16½	10 3
1887—8	2 3	9 8½
1888—9	2 7½	9 1½
1889—90	3 1½	8 11½

These figures I have taken from the official figures published by the Government.

I will now endeavour to explain how they have proceeded on the Continent, in order to accomplish these amazing results. In doing this I need not go back to the original Silesian beetroot and others which are to-day only of historic interest, but will direct your attention to the well-known contemporary experts in beetroot cultivation, Messrs. Vilmorin, Andrieux & Co., of Paris, and Messrs. Rabbethge & Giesecke, in Klein Wanzleben near Magdeburg.

Before proceeding further, I may at this point read a letter which I have received from Messrs. Vilmorin, Andrieux & Co., of Paris, on the subject of the selection of seed:—

"Dr. Gustaf Schaack-Sommer,

"Liverpool.

"DEAR SIR, "Paris, February 11th, 1891.

"We have read with great interest your pamphlet on the introduction of the sugar industry into the British Isles, and we are of opinion that it may be successful, as no climatal or economic conditions stand in the way of its development.

"Although the German beet seeds are of very good quality and widely used even in this country, we think that it is worth the while to experiment with the French strains, of which we should advise *three* as follows:—

"1st, *Blanche améliorée Vilmorin*.

"2nd, *Rose trative*. (Early red-skinned sugar-beet.) This, if inferior to the former variety in the proportion of sugar it contains, is remarkable in being the earliest of all known sugar-beets. The leaves become quite flat on the ground sooner than in most kinds, and the roots are ready for taking up about the middle of September.

"3rd, *Français à collet rose*. (Red top sugar-beet.)

"This last variety is nearly equal to *rose trative* in point of earliness and the yield per acre would be a good deal heavier. The proportion of sugar would be about 25 per cent. below that of "*Améliorée Vilmorin*," but the weight of roots per acre might be above the latter by one-third or even more.

"Now it is an important point to secure the co-operation of the farmers, and it might be no bad policy to try experiments with a variety that would give them a fair return in weight. The roots would be paid for more or less according to their industrial value, but we think the money return to the farmer would be rather higher with a large crop of roots of medium quality than with a fair crop of very rich roots.

"As no tax is put upon sugar in the United Kingdom, all the artificial conditions established on the Continent by the modes of levying the taxes and the premiums which result therefrom are unknown, and the variety can be chosen that gives best satisfaction to both grower and manufacturer."

In 1889 the roots grown from Klein Wanzleben seed succeeded best in my experiments, and this determined me to investigate on the spot the whole process of rearing the seed. Under the German fiscal system it has been to the advantage of the sugar manufacturer to grow a root as rich as possible in saccharine strength, and this led them to grow very small roots. The Klein Wanzleben people, however, were by no means satisfied with this arrangement, as they said that the farmer, being paid by weight, would obviously be a loser by only growing small rich roots. They therefore took the sensible way out of the difficulty, by directing their energies to the raising of a root that surpassed all others in the percentage of sugar per acre, thus meeting the demands of both the farmers and the manufacturers. Messrs. Rabbethge and Giesecke say that they have been rearing beetroot seed for 30 years, and that their plan is to select the mother-seed beetroots, by special methods, from the different families. In 1889 '90, for instance, they tested 2,782,300 beetroots, from which they selected 3,043 roots, or equal to 0.1 per cent., for rearing purposes. It is claimed for the original Klein Wanzleben roots that they give

the largest percentage of sugar per acre. I will give here the table published, and furnished to me, by Messrs. Otto Licht and Co., of the experiments of Professor Dr. Maereker, in Emmersleben, near Halberstadt, showing the comparative results of different kinds of seed for sugar beetroot.

Messrs. Otto Licht and Co. published figures in 1886 showing the results of experiments made by Professor Dr. Maereker in Emmersleben, near Halberstadt, showing strikingly the importance of the proper choice of seed.

Name.	Crop of Sugar Beetroot per Acre.	Sugar in the Beetroot.
	Tons. Cwt.	Per Cent.
<i>Vilmorin original</i> ...	11 5	16.3
<i>Heine</i>	13 2	17.0
<i>Duppe</i>	10 12	17.3
<i>Schreiber</i>	10 6	16.0
<i>Wanzleben original</i> ...	15 0	15.2
<i>Heine</i>	16 2	16.0
<i>Duppe</i> ..	14 2	16.3
<i>Schreiber</i>	15 12	14.9

His elaborate calculations, which take into account all costs, including the manufacture and farming, &c., show a net profit per acre for that year ranging from 6*l.* 12*s.* to 15*l.* 7*s.*, or a difference of 8*l.* 15*s.* In Germany that year 275,000 hectares (687,500 acres) were planted with sugar beetroot. Is it not amazing that even among these high class seeds the monetary difference for that Empire between the highest and the lowest would have amounted to 6,000,000*l.*, or for each factory, on a rough average, 15,000*l.*

It is the general custom in Germany that the manufactory supplies the farmers with the seed, and stipulates how they till, plant, and manure, or they put into their beetroot contracts a clause enabling them to refuse acceptance of roots which have a low saccharine strength, and paying higher prices for those that excel in this.

Another report by the same gentleman has been used by Messrs. Rabbethge and Giesecke in compiling a circular, which they have sent me, and where they show without doubt that all the sugar beetroots descending from the Klein Wanzleben root compare very favourably indeed with those descending from those of Mr. Vilmorin's rearing.

	A.—Sugar Beetroot descending from the Vilmorin Variety.	B.—Sugar Beetroot descending from the Klein Wanzleben Variety.
	Ctrs. Tons. Cwt.	Ctrs. Tons. Cwt.
Beetroot, per acre ...	242.57 = 12 2	301.62 = 15 2
Sugar per acre	38.47 = 1 18	15.45 = 2 5
	Per Cent. 15.80	Per Cent. 15.06
Quantity of sugar in 100 parts of beetroot		

After what has been said of the Klein Wanzleben root and its descendants, you will perhaps be surprised to hear that I am not at all certain that it is really the most suitable one for our English or the Irish climate. This is because it takes a rather longer time to get ripe than, for instance, the Vilmorin root, which has been reared in a cold soil and off cuttings. The difference between the two is almost six weeks; but then even the Vilmorin root can be prevented from ripening by being continually manured during the summer months with nitrate of sodium. This was the experience of a friend of mine who planted beetroot seed last summer in Cheshire, and who used too much artificial and stable manure, and who got small roots with enormous foliage, which yielded the following results on analysis:—

Date of Experiment.....	Geo. Cox, Esq. Grown in his Garden.	
	9th Sept. 1890.	15th Oct. 1890.
Number of beetroots drawn for experiment.....	2	1
Average weight with leaves, in grms.....	5.247	..
Average weight without leaves, in grms. .	269	..
Largest root with leaves in grms.	1,757	2,270
Largest root without leaves in grms.	310	620
Smallest root with leaves in grms.....	737	..
Smallest root without leaves in grms.	198	..
Specific gravity of juice.....	..	1.044
Degrees by Brix saccharometer
Quantity of sugar in 100 parts	Small	5.8
	Large	67.0
Quantity of non-sugar in 100 parts
Quotient of purity.....

This is a very singular property of nitrate that it keeps the roots from ripening, and, as I have said before, lime, phosphoric acid, and nitrate are very useful and essential manures for the beetroot, but they must neither be applied in too large quantities nor at the wrong time.

Some friends of mine, who are great authorities on this question, wrote to me last year after the publication of my paper that they thought I had recommended a too great

proportion of phosphoric acid, and that they thought that one of phosphoric acid to one of nitrate would be nearer the mark. Whereas my proportions were two parts of phosphoric acid to one of nitrate.

Here I may as well mention how the beetroots are chosen for rearing purposes. Every well-shaped and proper sized root is tapped with a narrow scoop similar to that used in taking a sample of cheese. The piece drawn is put in a glass filled with a salt solution of a density of from 16 to 18° by Brix saccharometer. If the piece sinks, the root is deemed worthy of further trials, if not it is placed along with others that are to go through the ordinary processes of manufacture. Before being chosen for planting out again in the following summer, two more pieces are bored out, and one water and one alcohol extraction and the usual polarisation made. With reference to my experiments last year I must premise that Mr. Licht recommended me to try—without, of course, discarding the roots with which I had been so successful on previous occasions—Vilmorin Nachzucht, and to compare the results with Vilmorin original, using each in equal proportions, to the extent of 30 lb. per acre. I am going to follow his advice, and have written to Messrs. Vilmorin, Andrieux, and Co., for seed, which they most generously furnished me with gratuitously and also wrote the letter which I have already partly read to you. This Vilmorin Nachzucht was reared by planting Klein Wanzleben and Vilmorin beetroot for seed rearing purposes side by side, and then after fructuation had taken place pulling the Vilmorin beetroots out.

Now I beg to lay before you the results of this year's experiments, and to say of the results I obtained that, as regards any comparison with Licht's reports, his roots were ripe while mine were not. The point to be determined is which root will ripen soonest, and it is with reference to this that the improved Vilmorin root must be considered.

RESULT OF THIS YEAR'S EXPERIMENTS.

This year my experiments were less satisfactory as far as saccharine strength was concerned in consequence of the dampness and coldness of the weather, but in weight you see I beat Mr. Licht's figures, as I did in saccharine strength last year.

I got a heavier root several degrees less in saccharine strength than Licht's. In roots drawn on the 9th of October

he got 16.47 per cent. of saccharine strength when I got only about from 13.0 to 14.06 per cent., and on the 21th of October, the last day I tested the root only contained 15.02 per cent. The average weight, in Licht's case, was 812 grms. with leaves and 478 grms. without, while mine were from over 1,000 and as high as 1,795 grms., with leaves, and without, 942 grms. In Ireland, on Mr.

Byrne's estate, Ballyknock, Ballynitty, co. Wexford, we got a quotient of purity, in spite of the big root, above that of Light at the same place.

The process of manufacture is as follows: The beetroots of which the tops have been cut off are brought to the yard of the factory where they are thrown into a trough in which water is running, through which they are propelled by an endless screw towards the factory. This is for the purpose of removing the dirt which is sometimes fully as much as

one-third of the actual weight of the beetroot, and even as high as 40 to 50 per cent. Having reached the factory the root is cut up by special machinery called beetroot-slicers. The pieces, cork-crow like in form, are then brought into one of the vessels of the diffusion battery where the sugar is extracted gradually by more or less concentrated solutions of luke-warm liquor from the other vessels of the battery, which generally consists of 12 vessels. The slices which have been thus treated, and which are then supposed to be

free from sugar, are squeezed through a conical-shaped patent press to extract the remaining moisture, and the residue is either fermented in the silos or dried by one of the numerous patent drying apparatus to make food for cattle. The saccharine extract is treated three times, twice with lime and carbonic acid and once with lime and sulphurous acid in order to remove both salts and colouring matter. In the present day animal charcoal is scarcely used at all in a beetroot manufactory. The products of these three treat-

ments are gathered through filter presses and the clear bright juice which is the final result of the process is boiled in a common vacuum pan to the point of crystallisation, which takes place in small wrought iron movable tanks, with the result of getting as a first product as much as 11.7 per cent. of the weight of the beetroot according to the figures furnished me from Klein Wanzleben. The crystallisation takes place in small square tanks larger at the top than the bottom and from these the centrifugal hydro-

extractors turn out the sugar ready for the market. The process, as you see, is a very simple one, and the expenses connected with it are very small indeed.

Of general interest will be the comparative cost of 1 cwt. of sugar made in Germany and in France in 1889-90, a statement I found in Mr. Hertz's excellent paper "Die Deutsche Zuckerindustrie," No. 2, 1891, and I recommend those who want full particulars to look them up there. He assumes in both cases that 1 m. 10 pf. is paid per cwt. of beetroot.—

Or an advantage to Germany of 79 pf. or 9d. per cwt. of sugar.

According to calculations I have made the cost of a beetroot sugar factory in this country, including the purchase of site, cost of buildings and machinery, allowing for contingencies, and providing working capital, would be in round numbers about 58,000*l*. The gross annual profits for 70 working days on 30,000 tons of roots would be 43,734*l*., and the net profit would be 4,495*l*., or $7\frac{3}{4}$ per cent.

on the capital of 58,000*l*. This $7\frac{3}{4}$ per cent., which is a very low estimate indeed, for I have valued the first product at 12*s*., the second and third product at 10*s*., and the molasses at 3*s*. per cwt., is the profit of making sugar out of beetroot, and the profit I mentioned in my paper last year, that is, 5*l*. 15*s*. 6*d*. per acre, and which, according to Professor Dr. Maereker and Messrs. Rabbelteige and Giesecke's figures was from 6*l*. 12*s*. up to 15*l*. 7*s*. per acre is quite separate. Here I may point out that in Germany

the sugar beetroot industry has had most beneficial results for the agricultural interest. Ten million marks are paid every year to South Bavaria for yoke oxen, and the residue of a hundred million roots is feeding over half a million head of cattle. The raw and finished products make nearly a million waggon loads, which of course is in itself a most important source of employment for unskilled labour. During the winter months 97,000 men find work in this industry, while in the early summer about a quarter of a million adults are occupied in the cultivation of the root. Nor is the benefit confined to labour, for machine manufacturers, coal miners, lime quarries, and brick works all feel the beneficial influence of improved business. Some people seem to be under the impression that this is an enterprise for large city capitalists, and not for the farmer, but the sooner they disabuse their minds of this idea the more likely is the project to assume a tangible and practical shape. The matter is one of national importance, especially to agriculture, and ought to be taken up in the first instance by landed proprietors, who would no doubt find ready co-operation among capitalists. On the Continent, and particularly in Germany and Austria, most of the factories are erected by landowners who, in many cases, allow the small farmers to participate in the undertaking by taking shares of various amounts, sometimes very small, but at the same time contracting to deliver roots for a series of years at a fixed price. This principle of co-operation seems to have worked marvellously well, for if on one side, owing to unforeseen circumstances, the farmer may not get such remunerative rates for his roots as he has been looking forward to, he may on the other side recoup himself from the results of the factory, and I recommend the same principle to the farmers of Great Britain and Ireland. In conclusion, I am desirous of impressing upon you as strongly as possible that this proposed industry is no delusive dream of over-speculative minds, but a practical business-like matter of the utmost national importance. I am anxious, therefore, to urge upon you the necessity of our all joining hands to create a new industry which will not only raise the English agricultural world from its present state of depression, but will likewise keep English money at home instead of enriching the foreigner. Let me repeat again and with all possible emphasis the moral of what I have said on this and previous occasions, that we can in this country produce beetroot sugar quite as well as they can on the Continent, and at rates remunerative enough to enable us to carry on a successful competition with the foreigner.

DISCUSSION.

The CHAIRMAN remarked that the importance of the subject could not well be over-rated. The introduction into this country of the manufacture of beetroot sugar produced on our own soil must be of very great value, not only as a matter of chemical industry, but of political economy. The apathy of the farmer could, however, only be got over by showing him that he could from a certain amount of soil obtain, in the shape of beet, something that would be at least equal to, if not better than, the product he was at present raising. He thought that the Society might bring its influence to bear in encouraging experiments and possibly by acting in concert with the Royal Agricultural Society so that experiments might be put on such a footing that the results obtained may have greater weight and induce agriculturists and manufacturers to take up the growth and treatment of the beet with vigour.

Professor CAMPBELL BROWN remarked that he learned a great deal from Dr. Schack-Sommer's paper. The question of manuring was a very important one, and he was much struck by the great weight of roots obtained in Ireland. He would like to know whether the crop was an exhausting one, and what weight of manure per acre it required to keep the soil from running down. Unless the soil was kept supplied, the crop could not continue to be grown, and it was important to know what crop they continue to get from the farm year after year, rather than what they could get in the first year.

Dr. HENDER said that the Society owed a debt of gratitude to Dr. Schack-Sommer for his papers on the sugar industry.

He had spoken of the apathy of the farmers, with whom he could, to some extent, sympathise. Before 58,000*l.* could be spent on capital for sugar works, they wanted to be sure of the other half of this industry, that was the beetroot growing, and farmers had to make the experiment. If the farmer were to make experiments what would be the return to him per acre for his outlay in the absence of sugar works? If the farmer could see his way to make the experiment pay, the apathy would not be so great.

Mr. POWELL thought that, interesting as the subject was from a chemist's or scientist's point of view, scarcely sufficient stress had been laid upon the commercial aspect of the matter. The facts marshalled by Dr. Schack-Sommer, and the results obtained under his direction were of so momentous a kind, that they affected the prosperity and social welfare of the largest industrial class in the kingdom, namely, the agricultural class.

It had been shown that even under what might be deemed amateur farming, so far as sugar-beets were concerned, England, and especially Ireland, could excel Germany and France both in weight of roots and richness of saccharine.

A new industry awaits the modern farmer, and he deserves neither sympathy nor help if he remains indifferent to the new conditions which Dr. Schack-Sommer's efforts have revealed to him as being within his reach. The moderate amount stated as being required to start a factory would be forthcoming if the farmers of any district evince a desire to adopt sugar-beet growing as a permanent industry. No effort should be spared to bring this subject before all classes of the people, and awaken the Government to a sense of its importance. The best thanks of the community were due to Dr. Schack-Sommer.

Mr. RHODES wished to ask Dr. Schack-Sommer, seeing the apathy of the English farmers, whether the Royal Agricultural Society and other similar societies would not be the persons to undertake experiments of this kind? It seemed to him that the question would want going into experimentally in a society like theirs, and it would be well to inquire whether other societies were doing anything in the matter. They knew that a certain amount of money had been voted for agricultural education in England, and he thought the experimental growth of beetroots for the production of sugar presented a suitable opportunity for expending some of that money in promoting a new agricultural industry.

Col. J. PIERKINGTON called their attention to Dr. Schack-Sommer's reference to the apathy of farmers, and pointed out that they must be led to see that they can venture out of their beaten track. He thought that if it could be shown that the farmer could have any means of disposing of those roots while he was experimenting as to the suitability of our own soil for cultivation, it would be well to go on with the matter. He would like to see a syndicate formed to take the matter in hand and to erect a small experimental factory, to show the public that the thing could be made to pay.

They all thanked Dr. Schack-Sommer for having taken a great interest in the matter, and for benefiting the industries of this country. They must have large sections of ground suitable to beetroot culture; from what he had heard it could be grown anywhere, and it was an impossibility to starve it. It could be cultivated when other cereals could not thrive, and his strong impression was that it would be a very good thing for the farmer if he took that into consideration. Prof. Campbell Brown had inquired whether the ground would bear crops for a long time. It would to a considerable extent. Every three years it was desirable to have some little change in the cultivation. The amount of manure required would not be great.

Mr. CROSFIELD thought that the magnitude of the interests at stake had possibly been somewhat overlooked. He stated that the consumption of sugar in the United Kingdom amounted to over 1,000,000 tons per annum, probably it was not less than 1,200,000, the money value of which was upwards of 15,000,000*l.*, a sum of money which the British nation had to pay exclusively to foreigners. As British colonial sugar had now almost ceased to be imported, although at one time it formed a large part of the sugar

supply of great Britain, he thought that if the fact was recognised that a portion at least of this sum could be retained in England, a considerable stimulus would be given to the suggested industry.

Mr. BECK remarked that the subject had been interesting, in so far as they had before them facts which were the first ground on which to work. Climatic influences were no impediment so far as the growing was concerned. If the farmer and factory would co-operate, antipathy would soon be overcome. One great advantage, apart from the commercial and monetary value, would be that every factory would form a school of agricultural education and science for the whole class of farmers, which would exert a beneficial influence on the knowledge of farmers for growing all kinds of crops.

Dr. SCHACK-SOMMER, after being questioned whether the Royal Agricultural Society would be disposed to do anything in the matter, said that at a meeting in June last, just before he read his paper in London, it was proposed by some members of the committee that a deputation should attend the lecture to represent the Royal Agricultural Society. The proposition was not accepted at the meeting. It was strongly recommended that members of the committee should attend the meeting to hear what he had to say, but they would not be officially represented.

In the subsequent issue of the Journal of Royal Agricultural Society, a treatise appeared which embodied all the experiments which he had made up to that date. If the Royal Agricultural Society did not wish to be officially represented, there was not much hope of help from that quarter. In reply to Dr. Hunter as to what the farmer could do with the beetroot if he had planted it, the lecturer stated that Mr. Gibbons had found that as cattle food it was a very valuable product, and Messrs. Peter Lawson and Son, Limited, seed growers and merchants in Edinburgh, had sent him yellow and red coloured sugar beetroots which they had grown there and some which were grown in Denmark for the sole purpose of feeding cattle. They said in their circular that on the Continent, and especially in Denmark, the valuable properties of beetroot for cattle feeding are thoroughly understood, and consequently this root is extensively grown for the use of milk cows, those kinds containing the largest percentage of saccharine matter—their most valuable feeding property—being the best for the production of milk and butter.

In fact it is well known that lately the lower qualities of sugar beetroot, that is, those which give large roots and do not contain so high a percentage of sugar, have been cultivated entirely for cattle-feeding purposes, as it has been proved that their feeding properties are about proportional to their saccharine strength.

Dr. Schack-Sommer, in conclusion, while thanking the meeting very heartily for the kind reception they had given to his paper, replied to a question of Professor Campbell Brown to the effect that continental experience has demonstrated conclusively that beetroot is not an exhausting crop; that, on the contrary, it increases the fertility of the soil if a proper rotation of crops is observed. In fact, it cannot be too fully impressed upon the agriculturist that the extraction of sugar removes from the beetroot scarcely anything else than what the plant has acquired from the atmosphere, that is, the carbonaceous material; thence it follows that all the material which the plant took from the soil is practically available for stock-feeding purposes on the farm, in the refuse from the sugar factory, and is consequently returned to the soil. This would also furnish an answer to the objection that might be raised in favour of the mangel crop as compared with the beet crop, to the effect that the former may sometimes be sold off the land as profitably as the beet crop. It must be remembered that in the case of the mangel there is no return to the soil, whilst practically all the ingredients that the beet takes from the land is returned to the farm in the factory refuse.

THE APPLICATION OF ELECTROLYSIS TO QUALITATIVE ANALYSIS.

BY CHARLES A. KOHN, B.Sc., PH.D.,

Assistant Lecturer in Chemistry, University College, Liverpool.

THE first application of electrolysis to chemical analysis was made by Gaultier de Claubry, in 1850, who employed the electric current for the detection of metals when in solution. Other early workers followed in this direction, and in 1861 Bloxam published two papers (J. Chem. Soc. **13**, 12 and 338) on "The application of electrolysis to the detection of poisonous metals in mixtures containing organic matters." In these papers a description is given of means for detecting small quantities of arsenic and of antimony by subjecting their acidulated solutions to electrolysis. The arsenic was evolved as hydride and recognised by the usual reactions, whilst the antimony was mainly deposited as metal upon the cathode. This electrolytic method for the detection of arsenic in which all fear of contamination from impure zinc is overcome, has since been elaborated by Wolff, who has succeeded in detecting as little as 0.00001 grm. of arsenious oxide by this means (this Journal 1887, 147).

In a somewhat different manner the voltaic current is made use of in ordinary qualitative analysis for the detection of tin, antimony, silver, lead, arsenic, &c. by employing a more electro-positive metal to precipitate a less electro-positive one from its solution.

The quantitative electrolytic methods of analysis, some of which I had the honour of bringing before the notice of the Society some time back (this Journal, 1889, 256), have placed a number of methods of determination and separation of metals in the hands of chemists which can be employed with advantage in qualitative analysis, especially in cases of medical and medico-legal inquiry. These methods are not supposed to supersede in any way the ordinary methods of qualitative analysis, but to serve as a final and crucial means of identification, and thus to render it possible to detect very small quantities of the substances in question with very great certainty. As such they fulfil the required conditions admirably, being readily carried out, comparatively free from contamination with impure reagents, and capable of being rendered quantitative whenever desired.

In conjunction with Mr. E. V. Ellis, B.Sc., I have examined the applicability of the electrolytic methods for the detection of the chief mineral poisons (with the exception of arsenic, an electrolytic process for the detection of which has already been devised, as described), viz., antimony, mercury, lead, and copper.

Antimony.—The method employed in the case of antimony is that adopted in its quantitative estimation by means of electrolysis, a method which ensures a complete separation from those metals with which it is precipitated in the ordinary course of analysis, arsenic and tin. This fact is of considerable importance in reference to the special objects for which these methods have been worked out.

The precipitated sulphide is dissolved in potassium sulphide and the resulting solution, after warming with a little hydrogen peroxide to decolorise any polysulphides that may be present, electrolysed with a current of 1.5–2 cc. of electrolytic gas per minute (10.436 cc. at 0° and 760 mm. = 1 ampere) when the antimony is deposited as metal upon the negative electrode. One part of antimony (as metal) in 1,500,000 parts of solution may be thus detected, a reaction 30 times more delicate than the deposition by means of zinc and potassium. The stain on the cathode, which latter is best used in the form of a piece of platinum foil about 1 sq. cm. in diameter, is distinct even with a solution containing $\frac{1}{2}$ mgrm. of antimony, and by carefully evaporating a little ammonium sulphide on the foil, or by dissolving the stain in hot hydrochloric acid and then passing a few bubbles of sulphuretted hydrogen gas into the solution, the orange-coloured sulphide is obtained as a satisfactory confirmatory test. The detection of 0.0001 grm. of metal can be fully relied on under all conditions, and one hour is sufficient to completely precipitate such small quantities.

Mercury.—Mercury is best separated from its nitric acid solution on a small closely-wound spiral of platinum wire. The solution to be tested is acidified with nitric acid and electrolysed with a current of 4–5 cc. (cc. refer to cc. of electrolytic gas per minute). The deposition is effected in half an hour. The deposited metal is removed from the spiral by heating the latter gently in a test-tube, when the mercury forms in characteristic globules on the upper portion of the tube. As a confirmatory and very characteristic test, a crystal of iodine is dropped into the tube, and the whole allowed to stand for a short time, when the presence of mercury is indicated by the formation of the red iodide, 0.0001 gram. of mercury in 150 cc. of solution can be clearly detected.

Wolf has applied this test under similar conditions, using a special form of apparatus and a silver-coated iron anode (this Journal, 1888, 451).

Lead.—Lead is precipitated either as PbO_2 at the anode from a nitric acid solution or as metal at the cathode from an ammonium oxalate solution. In both cases a current of 2–3 cc. suffices to effect the deposition in one hour.

Here again, 0.0001 gram. of metal in 150 cc. of solution can be easily detected. With both solutions this amount gives a distinct discolouration to the platinum spiral on which the deposition is best effected. As a confirmatory test the deposited metal is dissolved in nitric acid and tested with sulphuretted hydrogen, or the spiral may be placed in a test tube and warmed with a crystal of iodine, when the yellow iodide is formed. This latter reaction is very distinct, especially in the case of the peroxide.

Of the above two methods, that in which an ammonium oxalate solution is used is the more delicate, although it cannot be employed quantitatively owing to the oxidation of the metal that takes place.

An addition of 1 gram. of ammonium oxalate to the suspected solution is sufficient.

Copper.—0.00005 gram. of copper can be very readily detected by electrolysing an acid solution in the usual way. A spiral of platinum wire is employed as the cathode, and the presence of the metal confirmed by dissolving it in a little nitric acid, diluting with water and adding potassium ferrocyanide.

To detect these metals in cases of poisoning, the organic matter with which they are associated must first be destroyed in the usual way by means of hydrochloric acid and potassium chlorate, and the precipitates obtained in the ordinary course of analysis then subjected, at suitable stages, to electrolysis. As the solutions thus obtained will be still contaminated by some organic matter, it is necessary to pass the current for a longer time than indicated above. On the other hand, *urine* can be tested directly for these poisons.

The presence of mercury or of copper may be detected by acidifying the urine with 2–3 cc. of nitric acid (conc.), and electrolysing as described. 0.0001 gram. of metal in 30 cc. of urine can be detected thus, or 1 part in 300,000 of urine.

Lead does not separate well as peroxide from urine, but if ammonium oxalate be added, and the lead deposited as metal, the reaction is quite as delicate as in aqueous solution, and 0.0001 gram. of lead can be thus detected.

With antimony it is advisable to precipitate it first as sulphide, but it can be detected directly, though not so satisfactorily, by acidifying the urine with 2–3 cc. of sulphuric acid (dil.), and electrolysing with a current of 1–5 to 2 cc. In this case also it is precipitated as metal upon the cathode (cp. Chittenden, *Proceedings Connecticut Acad. Science*, Vol. 8).

In the presence of urine it is advisable to continue the passage of the current for about twice the time required in the case of aqueous solutions.

That an approximately quantitative result can be obtained under the above conditions was shown in several cases in which the deposition of 0.001 gram. of metal was confirmed with considerable accuracy, the spiral or foil being weighed before and after the experiment.

A comparison of the delicacy of these tests with the ordinary qualitative tests for antimony, mercury, lead, and copper by means of sulphuretted hydrogen, showed that

the two were equally delicate in the case of antimony and of copper, but that in that of mercury and of lead the electrolytic test was at least eight times the more delicate. These comparisons were made in aqueous solutions. In testing urine the value of the electrolytic method is still more evident, for here the colour of the liquid interferes materially with the reliability of the ordinary qualitative tests when only very small quantities of the metals referred to are present.

Beyond the detection of mineral poisons, qualitative electrolysis can only offer attraction to analysts in special cases, and the data on the subject are to be found in the many electrolytic methods already published. Beyond testing for gold and silver in this manner, I have not therefore examined the applicability of these methods further.

The detection of small quantities of gold and silver is of considerable importance, and advantage can be taken of the ease with which they are separated from potassium cyanide solution by the electric current for this purpose.

Silver.—Silver is obtained as chloride in the course of analysis. To confirm for the metal electrolytically, this precipitate is dissolved in potassium cyanide and the resulting solution electrolysed with a current of 1–1.5 cc. A spiral of platinum wire is employed as the anode, from which the silver may be dissolved by means of nitric acid, and tested for by hydrochloric acid or by sulphuretted hydrogen. 0.0001 gram. of silver in 150 cc. of solution can be detected thus, and one hour is sufficient for the deposition.

Gold.—Gold is deposited under similar conditions to silver from cyanide solutions. The deposit, which is rather dark coloured, can be dissolved in aqua regia and confirmed for by the Cassini's purple test. Here again 0.0001 gram. of metal in 150 cc. of solution can be detected without any difficulty.

As gold and silver are both extracted from quartziferous ores by treatment with potassium cyanide solution according to the MacArthur-Forrest process of gold extraction (this Journal, 1890, 267), this electrolytic method should prove very useful. By electrolysing the resulting solution a mixture of gold and silver will be deposited upon the cathode, which can then be parted by nitric acid and tested for as described.

DISCUSSION.

The CHAIRMAN said that there was little doubt but that further investigation into electrolytic methods of chemical analysis would give even more valuable results than those already obtained. Systematic investigations of the subject, such as have been given by Dr. Kohn, would go far to prove the adaptability of this method as a substitute for or aid in ordinary qualitative examinations. The remarks of Dr. Kohn respecting quantitative examinations were very interesting, and well worth following up by other practical work.

Professor CAMPBELL BROWN said that Dr. Kohn had shown that electricity brought the same kind of elegance, neatness, and simplicity into analysis that it did into lighting and silver-plating.

In its applications to the detection of poisons, he understood Dr. Kohn to say that the poisons must first be extracted by chemical means. That would not be sufficient, and he had no doubt that if the subject was pursued farther they would have a paper from him (Dr. Kohn) some day indicating that he had obtained arsenic and such poisons without the previous separation of the metal from organic matter. It was a very great desideratum to have a method for detecting arsenic and separating it from the contents of the stomach and food directly without previous destruction of the organic matter, and he hoped Dr. Kohn would pursue his work in that direction.

Dr. HUTTON said he was about to construct a new laboratory, and he would assure them that one of its arrangements would be the installation of electricity, by which to carry out researches similar to those described. He was very glad to learn that the presence of arsenic, &c. could be readily proved by means of electrolysis.

Dr. Koux, in reply, stated that he considered it would be a very difficult matter to effect the separation of the mineral poisons from organic matter electrolytically without the previous removal of the latter. The oxidation of the organic matter by the electric current was a slow process, and he did not think it was likely to be more complete or more effective than the means usually adopted. From experiments made with urine the decomposition of the organic matter present was fairly complete in a reasonable time, and this fact might be taken advantage of in the analysis of that product. But apart therefrom, he considered the methods worthy of some attention, as being a means of adding to the certainty with which very small quantities of the mineral poisons might be detected.

Meeting held Friday, April 3rd, 1891.

DR. BOWMAN IN THE CHAIR.

A SIMPLE AND RAPID METHOD OF GRAVIMETRIC ANALYSIS.

BY G. H. BAILEY, D.Sc., Ph.D., AND J. C. CHIN.

THE method is practically that by which the specific gravity of a solid would be taken, viz.:—by means of weighing in suspension in liquid. Although in this way the weight of the solid suspended in a liquid is frequently made use of as a means of determining its specific gravity, we are not aware that conversely the specific gravity (known or determined once for all) has ever been made use of for ascertaining the actual *weight* of a precipitate directly and without it being separated by filtration from the liquid. Some time ago Dr. J. Grossmann, a member of our Society, made some preliminary investigations in the direction indicated, but these were not published.

Description of Apparatus.

An ordinary specific gravity bottle might be used for the determinations, or even a 100 cc. flask. Indeed, the first part of our work was carried out with such a flask. The former, however, had its inconveniences, and the latter was too wide in the neck to admit of sufficiently accurate measurement. We therefore constructed a form of flask and fittings thereto which should overcome these difficulties. The 100

cc. flask is made in two parts, as shown in Fig. 1, the neck being in a separate piece and accurately ground into

Fig. 1.

Fig. 2.

the body of the flask. It is desirable, indeed, to make the neck almost capillary for the purposes of accurate reading, so that to facilitate the introduction of the liquid (and suspended matter) into the flask, it is necessary to make this capillary neck removable. With the arrangement shown in Fig. 2 it is easy first to fill the flask A with the liquid and precipitate and then fit in the capillary neck B, and add a little more liquid until a given mark on the stem is reached. The stem is furnished with graduations in millimetres. These serve not only to adjust accurately 100 cc. of liquid at 1 C., but also (the capacity of the stem being once for all determined) enabled us to get rid of the troublesome cooling (or warming) process used in specific gravity determinations where all weighings are made with the liquid at a given temperature. For instance, if the liquid at 1 C. (point of maximum density for water) stood at division 6 for 100 cc. liquid, and at 10 C. it stood at division 9, it is evident that when working at 10 C. the flask must be filled up to division 9 to represent 100 cc. of liquid at the point of maximum density of water. In order to further facilitate the introduction of the liquid containing the precipitate into the body of the flask, especially as 150 or 200 cc. of clear supernatant liquor had to be decanted off for another purpose, the cup-shaped vessel C, also ground so as to fit into the flask, is used.

Method of Working.

First, the specific gravity of the substance precipitated is carefully determined by ascertaining (a) weight of flask and air, and then deducting from this the weight of 100 cc. of air; (b) weight of flask and 100 cc. of water at 1 C.; (c) weight of flask filled to 100 cc. mark with water and the substance whose specific gravity was to be determined. The following values were obtained:

Silver chloride precipitated in the hot.....	5.298
Silver chloride precipitated in the cold.....	5.287
Copper oxide precipitated in the hot.....	6.514
Ferric hydrate precipitated in the hot.....	2.583
Barium sulphate precipitated in the hot.....	4.651
Barium sulphate precipitated in the cold....	4.642

Each of these values is the mean of several determinations which closely agreed amongst themselves. It will be seen that, as might be expected, the density of the product varies somewhat according to the circumstances under which the precipitation is effected. The determinations made in the hot were boiled for some time, as in the ordinary course of analysis, and the values were practically uninfluenced, as far as our experience goes, by prolonging

the period of boiling, or by the state of dilution when the precipitation is effected, at any rate within such limits as occurred in actual practice. In order, however, to make use of these numbers in the inverse manner for ascertaining the weight of a given precipitate, it is not necessary to replace the supernatant liquor by water, for, by using two similar flasks, 100 cc. of the clear supernatant liquor may be run off into one flask, leaving the precipitate and supernatant liquor occupying 100 cc. in the other flask. Some of the supernatant liquid may also be transferred to a small wash-bottle for convenience of washing down any precipitate which remains attached to the sides of the cup-shaped vessel. The actual determination of the weight of the precipitate W now takes this form:—

$$W = \frac{(w' - w) \times s}{s - W}$$

Where

- w' = weight of supernatant liquid and precipitate,
 w = weight of known volume (say 100 cc.) liquid,
 s = specific gravity of precipitate,
 V = volume of the flask (say 100 cc.).

As an instance of the weighings to be made, we give the following numbers, obtained in determining the amount of chlorine (as silver chloride) in a solution of common salt:—

Flask and liquid with silver chloride.....	123.551
Flask only (det. runned once for all).....	20.952
	<hr/>
	$w = 102.599$
	<hr/>
Flask and liquid.....	122.341
Flask only (determined once for all).....	21.724
	<hr/>
	$w = 100.617$
	<hr/>
$W = \frac{1.961 \times 520.8}{520.8 - 100.617} = 2.422 \text{ grms.}$	

Two weighings only are therefore required. The following numbers obtained by this method will show the extent of the variation which may be expected with careful working. The silver chloride determined gravimetrically was found to be 2.422 grms.

	Grms.
Experiment 1 gave.....	2.422
Experiment 2 gave.....	2.426
Experiment 3 gave.....	2.420
Experiment 4 gave.....	2.424

That is to say, the error in a chlorine determination, taking the value which shows the greatest divergence, will amount to less than one-twentieth per cent. It is not, of course, contended that the method is to be preferred to the ordinary gravimetric determination on the score of accuracy, but rather that it effects a saving of time, especially where a number of similar determinations have to be made from day to day, and where the amount of material is sufficient to yield a precipitate of 2 or 3 grms. As a matter of fact, a determination may be made, after the precipitation has been effected, in half an hour, and a dozen similar determinations done simultaneously in a dozen flasks would occupy very little more additional time than that required to make the necessary weighings. Of course the analysis of a substance involving several determinations—such as the iron, copper, and sulphur in cupreous pyrites—can be made quite as readily. A determination of iron and sulphuric acid in a solution of ferrous ammonium sulphate gave the following results:—

	Found	Calculated.
Fe.....	0.842	0.8234
SO ₄	2.784	2.758

The following observations have suggested themselves in the course of working out the details of this method of analysis:—(1.) Where the precipitate forms a double salt with any of the substances existing along with it in the solution, regard must be paid to this (as it must also in the

gravimetric method) and precautions taken. Some soluble salts (the alkalis, for instance, by barium sulphate) are readily carried down with the precipitate where the solution is a concentrated one, and must be washed out with hot water. It is best, however, to precipitate with the precautions usually observed, using dilute solutions. (2.) The method can only be recommended where a sufficiently large quantity of precipitate is obtainable—say 2 grms. Of course it is possible to work with small quantities, but then the experimental error becomes large, unless greater care is exercised than is to be expected in routine determinations. (3.) For determinations where the precipitate can not be washed free from the other liquor without loss, this method may be recommended as preferable to the gravimetric method. Such are the determinations of fluorides, borates, phosphates, and several of the more troublesome sulphides. In the latter case the precipitation can be effected by passing the sulphuretted hydrogen directly into the flask, and thus all fear of alteration by oxidation, &c. is avoided.

NOTES ON EFFLUENT WATER ANALYSES AND ON METHODS FOR DETERMINING THE VALUE OF RIVAL PROCESSES FOR THE PURIFICATION OF SEWAGE.

BY WILLIAM THOMSON, F.R.S.D., F.I.C., ETC.

HAVING lately been engaged in the study of these questions, I have been asked to bring the matter before the Section for discussion this evening.

The subject is one which at the moment is of special interest to the people of Manchester, Salford, and to the residents near the streams which will in future go to supply the Manchester Ship Canal. It is also of great importance to the whole of the country as the statutes with regard to the pollution of rivers are every day being more stringently enforced, and attempts must be made to find the best practical process for sewage treatment.

The refuse matters which at present find their way into rivers and sewers may be classed under two heads:—(a) the ordinary household sewage; and (b) refuse from manufactures.

The first can be estimated at so much per head of the population, and is that with which the people of England, generally speaking, are more particularly concerned. The second differs very greatly both in quality and quantity, and in this the manufacturers are chiefly interested. Ordinary town sewage consists of organic and mineral matters in suspension and in solution, and the problem which the chemist and engineer is called upon to solve is to find the most efficient method at the smallest cost of removing the suspended matter (both organic and inorganic) on the one hand, and as much of the organic matter in solution as possible on the other. It is not so material to remove the mineral matter in solution because that would not be a matter of much importance so far at least as the Manchester Ship Canal is concerned.

The treatment of sewage by sewage processes aims at the more rapid precipitation of the suspended matters, both organic and inorganic, by the addition of something to it, or by a similar operation to bring the suspended matter into a condition in which it might easily be removed by filtration, as town's sewage usually contains somewhat slimy matters in suspension which are liable to block the filters.

The second thing which is demanded of the sewage process is that it shall as far as possible remove organic matters from solution, because if all the objectionable suspended matter be removed the organic matter left in solution would in warm weather undergo putrefaction and emit very objectionable smells.

In comparing rival processes for producing the results above mentioned, one thing is of the very first importance, and that is that each process shall be made to act upon sewage of precisely the same quality. Sewage as it flows through the sewers differ in quality every few minutes, and it is evident that an average sample could not be obtained by taking samples every minute, although samples have usually been collected by those making such investigations every 5, 10, or 15 minutes, and in recent experiments which were made, the results of which were printed but not circulated, the samples of raw sewage were taken every half-hour and mixed together to give an average sample: that this did not give average samples is abundantly proved by looking at the figures obtained by the analysis of the crude or raw sewage in comparison with the figures obtained for the effluents. In some cases the raw sewage appears to be actually purer than the effluent produced after treatment.

There are two and only two methods for finding the relative value of sewage processes. The first is to have a tank say about five yards square fitted with agitators such as those used for keeping flour and water mixed for the preparation of size for warp sizing. The rival processes should then be arranged on each side of this tank; when the tank has been filled with the sewage and thoroughly mixed, a good sample should be taken to be reserved for analysis and experiment, as compared with the same sewage after treatment by the different processes. One analysis of raw sewage would therefore be sufficient for all the processes.

The tank should be provided with taps or sluices on each side so that the same quantity of sewage should be delivered at the same time to each of the different systems at the same rate, say 2,000 to 3,000 gallons per hour, each rival apparatus being made on a scale to treat such an amount.

First comes the determination of the relative values of the different processes as regards their respective influences in aiding the separation of the suspended matter. Assuming four processes are to be tested, five calico or woollen bags of the same size should be taken, and say one or two gallons of the thoroughly mixed raw sewage poured into one, and the same quantity of the same sewage, immediately after treatment by each of the different processes (also well stirred up), should be poured into each of the other four bags, and the time required for each to filter through accurately noted, and the quality of the filtrate in each observed as to clearness or turbidity.

These filtrates might then be analysed to find—

(a.) Total solid matter in solution, together with any impalpable sediment which might be left in suspension after passing through the filter.

(b.) Loss on ignition of the above after drying at 220° F.

(c.) Free and albuminoid ammonia.

(d.) Permanganate of potash required to oxidise organic matter, &c., acting during say 15 minutes, and after acting during say three hours, at a temperature of 90° F.

(e.) The combined chlorine.

(f.) The combined sulphuric acid.

(g.) The quantity of iron or alumina in solution, if any.

(h.) The condition of the filtrates as regards acidity or alkalinity, the amount of acidity or alkalinity being determined, using lacmoid as indicator with $\frac{N}{50}$ sulphuric acid or $\frac{N}{50}$ soda.

(i.) Two 10-oz. stoppered bottles (as duplicates) about two-thirds full of each filtrate might then be put aside and examined every day to find how long each remains, under the same conditions, without emitting a putrid odour.

(k.) Five large glass cylinders of similar dimensions, each holding, say, one to two gallons, might be filled, one with the stirred raw sewage, and one with sewage from each of the processes after treatment, but before being allowed to settle.

These might each be provided with a glass rod, and after all had been thoroughly agitated, the time required for settlement or subsidence so as to leave a clear supernatant liquor observed. After a certain time a portion of each might be syphoned off from the same depth, and the suspended matter still left in it estimated.

These operations would give the effect of the precipitant used in each process, both from a chemical and from a mechanical point of view.

The next process would be to weigh the sludge or matter left in the filter. This might conveniently be done by having each bag carefully dried and weighed in a tared beaker covered with a glass plate or india-rubber cap before and after filtration; the difference would be the sediment or sludge produced by each process.

(l.) These sediments might then be analysed to find specially what percentage of iron and alumina was contained in them. This would give a good idea of the quantity of iron and alumina, or both, used for precipitation, and especially in the electrical process, where the quantity of iron used up was determined by weighing before and after using, a large quantity of heavy cast-iron plates.

The quantity of lime or other precipitant employed might also thus be determined in the sludge filtered off.

The above, however, does not show the value of each of the processes. In the electrical, and in Barry's and Spence's, the process, after treatment, is complete with the exception of the required settlement and filtration. The international process, however, is at this stage said only to be half finished, and the patentees claim that a filter which they possess has the power of still further oxidising and removing the organic matters from solution. It is evident, therefore, that for the completion of the tests, the effluent from each process must be analysed in the same manner as the filtrate above mentioned.

The figures thus obtained would give a very good idea of the value of each process, as the raw sewage dealt with would be absolutely the same for each.

All these experiments should be made in strict comparison with the raw sewage, because I observed in the printed results I have mentioned of trials of four sewage processes made recently in Salford that the raw sewage is first analysed, and the difference between it and the effluent is credited to the process through which it has passed, whereas if the raw sewage had been simply left to subside and then filtered through sand, there might be really very little difference between it and that obtained by any given process.

It might be contended, however, that it is no practical test of any sewage process to try the effect of each on, say, 2,000 or 3,000 gallons, because it might be suggested that the quantity of electricity used in the electrical process might be greater for the small quantity of sewage employed than it could be for larger quantities, or that the filters which oxidise might become clogged or lose their effect by continued use. If it be desired, then, to work for some time continuously each process, then the *second arrangement* might be employed. This would consist of a large tank provided with stirrers, into the centre of which should fall the sewage to be tested, the stirrers being kept constantly at work, and the sewage being supplied from the bottom of the different sides of such tank, one opening being also arranged for allowing the untreated sewage to flow out into a tank similar to those in use for treating the sewage; this to give a raw sewage standard for comparison, so that at any time samples of the effluent from each process might be taken and compared with a sample of the raw sewage, which at any time would as nearly as possible represent a true sample of the sewage which would be treated by all the different processes.

By such a method as this an almost mathematically correct comparison could be obtained of the action of the different processes on sewage. It would of course go without saying that the analysis of all the samples should be made immediately after being taken, before any subsequent change could take place in them.

No such method as either of those above mentioned were carried out by the committee of chemists and engineers in the tests which were recently made of the four different processes tested with the Salford sewage. In these experiments each process was worked on the sewage separately, the one after the other, samples of the sewage supplied being taken as it flowed to the treating tanks or vessels every half-hour, and the whole mixed together and a sample taken from it as representative of the sewage which was treated.

Here, for instance, are some of the results given, which shows the importance of knowing the exact composition of the sewage actually treated.

	Parts per 100,000.
Albuminoid Ammonia.	
Sample No. 1: Raw sewage (before treatment).....	0.750
Sample No. 2: Same sewage in tank (after treatment).....	0.780

This is an example in which the albuminoid substances are greater after than before treatment, which could presumably only be accounted for by the fact that the sample of raw sewage taken, did not represent that which was treated. Here is another of the same kind:—

	Ammonia.	Oxygen taken up in Three Hours.	Mineral and Organic Matter in Suspension.
	Free.	Albuminoid.	Solution.
Sample 41: Raw sewage (before treatment).....	1.53	0.530	4.0 25.0 156
Sample 42: Sewage (after treatment).....	1.55	0.70	5.0 35.2 161

The interpretation of the results of the analyses has led to a curious misapprehension on the part of the engineers as to the meaning of the figures given by the analysts. Thus, the loss on ignition is described as "organic matter." Most chemists write "organic matter, &c.," the loss being as a rule principally the "et cetera"; in other words combined water, ammonia salts, chlorine from chloride of magnesium, and perhaps some volatilised common salt. Now, on treatment by any of the processes in which iron or alumina are employed, some hydrated oxide of iron, sulphate of lime, or other compound is added or formed which contains a large percentage of combined water, and thus it comes that "organic matter" is represented as contained in greater quantity in the effluents than in the raw sewage.

Now comes the engineers' report, and they take the chemist's figures for organic matter which is not organic matter at all, but chiefly "et cetera," and they cite these results as follows:—

	Parts per 100,000 Organic Matter in Solution.
International process.	
One example Raw sewage.....	43.5
Effluent after filtration.....	50.0
Another example Raw sewage.....	24.2
Effluent after filtration.....	17.6
Electrical process.	
One example Raw sewage.....	11.4
Effluent after filtration.....	1.77
Another example Raw sewage.....	11.4
Effluent after filtration.....	26.8

It is interesting to see how the engineers explain these results. They say in their report, "In none of the cases, however, can the results be considered entirely satisfactory in respect to the solids remaining (more especially the

organic solid-) in solution, and it is somewhat remarkable that these were increased instead of diminished. The precipitants, added to the volume of sewage, may partially account for this, and impurities existing in the filtering material may possibly account for the remainder."

One of the chemists, in epitomising his results, takes account of this loss on ignition as organic matter. Thus, he shows in the four processes the following figures:—

	Mean Percentage of Purification.
	Loss on Ignition. "Organic Matter in Solution."
International.....	— 9.5
Electrical.....	— 11.65
Spence's.....	+ 16.45
Barry's.....	+ 26.95

The minus sign means that the loss on ignition from the soluble matters in the mean of the effluents were less than that contained in the mean of the sewages employed. The + sign means that the loss on ignition in the effluents was greater than it was in the filtered raw sewages. As far as I can make out, the first figure in this table is a serious mistake in calculation from the figures given in the body of the report; the figures should be much higher.

Citing from the figures of the report further, I give as follows "percentages of purification," as shown by free and albuminoid ammonia, and "oxygen taken up in three hours."

	"Percentages of Purification."	
	Ammonia.	Oxygen taken up in Three Hours.
	Free.	Albuminoid.
International.....	83.47	— 79.51
Electrical.....	— 26.75	— 60.00
Spence's.....	+ 56.44	— 47.38
Barry's.....	+ 28.37	— 33.75
		Could not be determined.

Putting aside the figures obtained as "loss on ignition," called "organic matter," as of no value, we come to the free and albuminoid ammonia and oxygen required to oxidise the organic matters, and we observe that the international process shows, by his figures, a much higher percentage of purification than the electrical process, and in this view it is difficult to reconcile his remarks, which I give as follows:—

"After studying closely the results of my analysis . . . and the results of some laboratory experiments, also taking into consideration the uniformity of its working, I am of opinion, as the final result of my investigation, that the most reliable process is that of the Electrical Purification Association (Limited)."

It appears as if Mr. Carter Bell and the other chemists employed had not compared results before printing, but Mr. Bell's figures confirm the referee chemist in showing that a greater amount of purification was effected by the international than by the electrical process, but he has wisely abstained from deciding between these two processes from the figures he obtained, considering the unsatisfactory and unscientific conditions under which both appear to have been compelled to work. The net result of the whole of the work done in this investigation to find the relative values of the different processes is that it is practically valueless.

MR. JOHN PATTINSON IN THE CHAIR.

ON THE DETERMINATION OF MANGANESE IN ITS ORES AND ALLOYS.

BY JOHN PATTINSON, F.R.C., AND H. SALVIN PATTINSON, PH.D., F.R.C.

Owing to the large quantity of manganese in the form of spiegeleisen and ferromanganese, now used in the manufacture of steel, the accurate estimation of this metal in its above-mentioned alloys and in the ores from which these alloys are made, is of considerable industrial importance.

The gravimetric methods of estimating manganese usually adopted may be classed under three heads: 1. Those in which the manganese is calculated from the manganoso-manganic oxide (Mn_2O_3) obtained by igniting the carbonate or the hydrated dioxide in air; 2. Those in which the manganese is weighed as pyrophosphate; 3. Those in which it is weighed as sulphide.

In all these methods the solution of manganese before precipitation of the manganese is freed from iron and aluminium by some one of the various ways in which this can be done, but the process now usually adopted is to precipitate the iron and aluminium by ammonium acetate. The filtrate from this precipitate then contains the manganese and any copper, nickel, cobalt, or zinc, together with a small quantity of iron that has escaped separation. In the case of manganese ores and manganiferous iron ores, the solution also usually contains calcium, magnesium, and alkalis. If the manganese be now precipitated with bromine and ammonia, the precipitate of hydrated manganese dioxide carries down with it, as is now well known, portions of all these substances, which must afterwards be separated from it and their weight deducted from the total weight of the precipitate. Or the iron, zinc, copper, nickel, and cobalt may be separated before the manganese is precipitated, by rendering the solution slightly acid with acetic acid and saturating it with sulphuretted hydrogen. We would point out that although, no doubt, the greater part of these substances may be separated in this way, nevertheless it is most difficult to ensure their complete separation from a relatively large quantity of manganese. In fact, unless the solution is so very slightly acid that a portion of the manganese itself is precipitated, we find that there is incomplete precipitation of the other substances. In the case of ores the calcium, magnesium, and alkalis still remain in solution with the manganese after the removal of the other substances by sulphuretted hydrogen, and the separation of

these is very troublesome, necessitating the precipitation of the manganese as sulphide, or the dissolving out of the calcium, &c. from the precipitated manganese oxide by nitric acid, and these processes are but imperfectly successful.

When the manganese is weighed as pyrophosphate, the same objection obtains, for it is usual to first precipitate as hydrated dioxide and, after redissolving this precipitate, to reprecipitate the manganese as phosphate. Unless the calcium and magnesium have been separated, these of course are precipitated as phosphates with the manganese.

H. Rose has suggested the weighing of the manganese as manganese sulphide formed by igniting the oxide with sulphur in an atmosphere of hydrogen. This method is still open to the objection that it depends in the first place upon the formation of the hydrated dioxide, and the tedious separation of all other substances carried down with the dioxide precipitate, is not avoided.

No doubt fairly accurate results may be obtained by the gravimetric process when the manganese is weighed as pyrophosphate or as sulphide, provided of course that due care has been taken to separate all impurities from these substances; the methods are both very tedious and require very experienced manipulation to give anything like good results. But when the manganese is weighed as manganoso-manganic oxide (Mn_2O_3) a still further risk of error is incurred.

We refer to the fact, first pointed out by Wright and Luff (Journal Chem. Soc. Trans. 1878, 525), that when manganese carbonate, or the higher or lower oxides of manganese are ignited in air, a product is obtained which invariably contains more oxygen than Mn_2O_3 , and that only by long continued heating over a powerful blast lamp can a product approximating closely to Mn_2O_3 be obtained. Pickering (Chem. News, 43, 225) found that when hydrated manganese dioxide was heated in a platinum dish over an ordinary Bunsen burner, the composition of the resulting oxide varied with the temperature, approximating when heated during the day, with a low gas pressure, to Mn_2O_3 , and at night, with a better gas supply, to Mn_2O_3 , but that the variation in composition at the higher temperature was from 70.35 per cent. to 74.99 per cent. of manganese, pure Mn_2O_3 containing 72.05 per cent. of manganese.

Dittmar, in 1864 (Jour. Chem. Soc. 1864, 295), had already shown that when manganese dioxide was heated to dull redness in air or even in an atmosphere of nitrogen, the resulting oxide approximated to the composition of the sesquioxide Mn_2O_3 , and not to that of the protos sesquioxide Mn_3O_4 .

Notwithstanding these well-known facts we believe that it is still not an uncommon practice among chemists to estimate manganese by precipitating it as hydrated dioxide, and after ignition of this precipitate at a red heat until a constant weight is obtained, calculating the percentage of manganese on the assumption that the product of ignition has the composition Mn_2O_3 , and without making any correction for the oxygen it contains in excess of that required to form manganese protoxide, MnO .

We have had occasion during the last two years to repeat, to a partial extent, the investigations of Wright and Luff and of Pickering, on the products obtained by heating hydrated manganese dioxide in air, and whilst we confirm the work of these chemists on this subject, we think our results are of sufficient interest to warrant our publishing them, especially as they have an important bearing upon the determination of manganese.

Our experiments were made with manganoso-manganic oxide of known composition, prepared either from crystallised manganese sulphate or from ferromanganese containing about 82 per cent. of manganese.

The manganese sulphate was recrystallised, and after solution in water the manganese was precipitated with ammonium sulphide; the precipitate was thoroughly washed to remove a small quantity of lime that was present in the manganese sulphate, and it was then dissolved in hydrochloric acid, the solution filtered from separated sulphur, and evaporated to dryness to expel the excess of acid. The residue was dissolved in water, boiled, and the manganese precipitated as carbonate with ammonium carbonate. After

washing the precipitate free from chlorides the manganous carbonate was dried, separated carefully from the filter paper, and ignited in a platinum dish in a gas muffle, for several hours at a very bright red heat, approaching a white heat, until the weight of the dish and its contents was constant. The resulting oxide was then carefully examined and found to be free from any impurity, and the oxygen in excess of that required to form manganous oxide, determined.

It was found to contain —

	Per Cent.	
MnO ₂	93.93 = 72.05	Mn.
Available oxygen.....	6.97	
	<hr/> 100.00	

Pure Mn₂O₃ contains 72.05 per cent. of manganese and 6.99 per cent. of available oxygen.

There being some difficulty in obtaining manganese sulphate sufficiently free from aluminium and calcium, and small quantities of the latter being especially difficult to separate from manganese, we made another batch of Mn₂O₃ from ferromanganese containing about 82 per cent. of manganese. In this substance all the impurities carried down with the precipitate of hydrated manganese dioxide, by precipitation with bromine and ammonia, were such as could be removed or estimated by precipitating them as sulphides in acetic acid solution.

The ferromanganese was finely pounded and then dissolved in hydrochloric acid, and the solution filtered from the separated carbon and silica. The clear solution was then evaporated to dryness in a platinum dish, and dried in an air-bath at about 130 °C. for three hours. The residue was transferred to a beaker and dissolved in water and a little hydrochloric acid, and the solution filtered from a trace of silica. The filtrate was then boiled and the iron oxidised with nitric acid. The iron was next removed as basic ferric acetate by precipitating it with ammonium acetate, and the filtrate from the iron precipitate was made very nearly neutral by adding ammonia until the solution barely showed any acidity when tested with litmus paper. The liquid was then boiled and saturated whilst hot with sulphuretted hydrogen. Some of the manganese was carried down with the precipitate of sulphides of iron, copper, and nickel which formed, but it was found that unless the solution was so nearly neutral that some small part of the manganese was also precipitated, there was a very imperfect

separation of the other substances. The sulphuretted hydrogen precipitate was filtered off, the filtrate boiled to expel the sulphuretted hydrogen, and the manganese was then precipitated as carbonate with ammonium carbonate. After thoroughly washing the carbonate, it was dried and calcined in a gas muffle at almost a white heat until the weight was constant. Before a constant weight was obtained it was found necessary to grind the oxide in an agate mortar and to stir it frequently during the calcination. The resulting oxide was carefully examined and found to contain—

	Per Cent.	
MnO ₂	92.92 = 71.98	Mn.
Available oxygen.....	7.01	
Ferric oxide and traces of copper and nickel oxides,	0.07	
	<hr/> 100.00	

Pure Mn₂O₃ contains, as already stated, 72.05 per cent. of manganese and 6.99 per cent. of available oxygen.

The behaviour of manganese carbonate, formed as above described, when heated at various temperatures in a gas muffle furnace was examined as follows:—

About 115 grains of the dried manganese carbonate were placed in a tared platinum crucible, and first of all heated for 1½ hours at a dull red heat, the crucible being placed in the mouth of the muffle. At the end of this time it weighed 72.985 grains. The upper layer of the substance was then found to be black, whilst the underneath layer next the crucible was of a red-brown colour. It was then crushed up and stirred by a flat-ended glass rod, and again heated at a dull red heat for one hour, when it was found to have gained 0.75 grains, and now weighed 73.735 grains. At the end of this second period of heating, its colour throughout appeared uniformly black, but on grinding the contents of the crucible up in an agate mortar it was seen that there were still small particles which although black outside were red-brown inside.

Some of the black oxide prepared in this way in a previous experiment was found to closely approximate to the composition of Mn₂O₃.

After grinding in an agate mortar the quantity of substance returned to the crucible was first weighed, and, owing to some loss during the grinding, it weighed 73.41 grains. The heating was then continued as shown below.

TABLE I.

22	120	Do. very dull red heat	71.53	Do.

The available oxygen was now determined in this product, and found to be 7.035 per cent.; pure Mn_2O_3 contains 6.99 per cent. of available oxygen.

On examining this table it will be seen that when heated at a dull red heat in a gas muffle, manganous carbonate, after parting with its carbonic acid, absorbs oxygen until it attains the composition of Mn_2O_3 . The available oxygen in the final product, 7.03 per cent., shows that after the sixth and seventh heating the substance contained 10.17 per cent. available oxygen, as compared with 10.13 per cent. required by Mn_2O_3 .

It will be remembered that in the Dunlop manganese recovery process, when the manganese carbonate is heated at a much lower temperature than a dull red heat (about 600° F.) in the presence of water vapour, a still higher oxide than the sesquioxide is formed.

It is further seen that after alternately heating strongly and then at a dull red heat, the substance after each exposure to a high temperature absorbs less oxygen on exposure to a low temperature than it had done on the last exposure to a low temperature, until finally a molecular condition is reached in which it ceases to absorb or to lose oxygen, and that its composition in this condition, by making the higher temperature sufficiently intense, may be made closely to approximate to Mn_2O_3 .

Twenty grains of the manganoso-manganic oxide made from manganese sulphate were dissolved in hydrochloric acid, the solution diluted and saturated with bromine. Ammonia was then added and the precipitate of hydrated manganese dioxide filtered off on a Schleicher's filter paper, and washed until free from chlorides, and dried. The precipitate was separated from the filter paper, which was burnt off in a tared platinum crucible, and the precipitate was then placed in the crucible and heated for successive periods as shown in the following table.

TABLE II.

5	Do.	20.00	..

The available oxygen in this substance was then determined and found to be 6.98 per cent. The theoretical yield of available oxygen from Mn_2O_3 is 6.99 per cent., and the manganoso-manganic oxide used in the experiment yielded 6.97 per cent. of available oxygen.

It will be seen that after heating at a bright red heat for about an hour and a half the substance was reduced to the composition of Mn_2O_3 . But had the weight been taken after heating for 20 minutes at a bright red heat and the assumption made that the substance was Mn_2O_3 an error of about 0.8 per cent. of manganese would have been made.

Another portion of 20 grains of pure manganoso-manganic oxide, containing 6.97 per cent. of available oxygen, as against 6.99 per cent. required by theory, made by heating the carbonate as already described, was heated in a platinum crucible in the following way.

TABLE III.

Duration of successive periods of Heating.	Manner of Heating.	Weight in Grains after Heating.	Loss in Weight in Grains on previous Heating.	Gain in Weight in Grains on previous Heating.
Minutes.				
5	Over gas blow-pipe in clay jacket.	19.98	0.02	..
5	Do.	19.96	0.02	..
10	Do.	19.85	0.11	..
8	Do., gas pressure greater and temperature very high	18.93	0.92	..
1	Gas muffle at bright red heat.	19.91	..	0.98
30	Gas muffle dull red heat.	19.95	..	0.04
30	Do.	19.97	..	0.02
30	Do.	19.97

The platinum crucible in which the substance was heated was not a thin one, but on the contrary one with stouter sides and bottom than those that are usually made. It will be seen, however, that there was a considerable loss of oxygen caused by heating over the blow-pipe in a clay jacket, equivalent to as much as 3.85 per cent. of manganese if the weight 18.93 grains be taken as Mn_2O_3 . On examining the substance in the crucible when it weighed 18.93 grains, it was found that the underneath part, next the heated metal of the crucible, was of a green colour, no doubt owing to reduction of the manganoso-manganic oxide to manganous oxide, probably, as suggested by Pickering, owing to reducing gas permeating the heated platinum. On placing the crucible with its lid off in a gas muffle furnace for about three-quarters of a minute, at a bright red heat, that part of the substance which was green began to glow and continued

to do so for about half a minute. After the glow had ceased, the crucible was taken out and weighed and found to have gained in weight 0.98 grains, and after heating for an hour longer it ultimately nearly acquired the original weight of the manganoso-manganic oxide used. This experiment shows that there is a risk in heating manganoso-manganic oxide strongly over a gas blow-pipe of obtaining an oxide containing less oxygen than Mn_2O_3 . We have also found that sometimes reducing gases enter the mouth of the crucible even if closed by a good fitting lid, when a gas blow-pipe and clay jacket are used. This corresponds with an observation of Wright and Luff (Jour. Chem. Soc. Trans. 1878, 534) when endeavouring to obtain cobalt monoxide by heating a higher oxide in an atmosphere of carbon dioxide over a gas blow-pipe.

The following experiment shows that the precipitate of hydrated manganese dioxide formed by bromine and

ammonia behaves in the same way as the oxide derived from manganoso-manganic oxide when heated alternately at high and low temperatures, absorbing oxygen at the lower temperatures and parting with it at the higher temperatures, but in this experiment the substance was exposed to the heat of a blast-lamp and the final product contained an amount of oxygen less than that required to form Mn_2O_3 . The experiment also shows the tendency of the precipitate of hydrated manganese dioxide to carry down with it calcium from solution.

Twenty grains of manganoso-manganic oxide, containing 6.27 per cent. of available oxygen and 93.03 per cent. of MnO , were mixed with 3.57 grains of calcium carbonate = 2 grains CaO , and after solution in hydrochloric acid and dilution with water, the manganese was precipitated with bromine and ammonia, and the precipitate filtered off, washed free from chlorides, dried and heated in a platinum crucible as follows:—

TABLE IV.

No.	Duration of successive Periods of Heating.	Manner of Heating.	Weight in Grains after Heating.	Loss in Grains after Heating.	Gain in Grains after Heating.	Colour of Substance.
	Minutes.					
1	15	Large Bunsen burner	20.45	Light brown.

10	10	Blow-pipe in clay jacket	19.96	0.25	..	Colour next crucible rather light brown, one piece green.
11	2	Bunsen burner	20.01	..	0.18

After the last heating the available oxygen was determined in the product. To do this it was finely ground in an agate mortar and 19.92 grains of it weighed off and dissolved in a solution of ferrous sulphate in sulphuric acid, and the excess of ferrous salt titrated with standard potassium dichromate solution.

19.92 grains of the substance yielded 1.2017 grains of oxygen; therefore 20.01 grains, *i.e.*, the whole of the substance, would yield 1.248 grains of oxygen. Deducting 1.248 from 20.04 we have left 18.792, which is the weight of MnO and CaO in the 20.01 grains of the precipitate. But the actual amount of MnO taken for the experiment was only 18.606 grains (20 grains of the original Mn_2O_3 containing 93.03 per cent. MnO), therefore the quantity of lime present in the precipitate is

$$18.792 - 18.606 = 0.186 \text{ grains.}$$

and the composition of the precipitate is—

	Grains.	Per Cent.
MnO	18.796	92.84
Available oxygen	1.248	6.23
CaO	0.186	0.93
	20.230	100.00

Had the weight after heating for 15 minutes on the Bunsen burner and then for 30 minutes at a bright red heat in the gas muffle, been taken as representing the weight of Mn_2O_3 found in the analysis of a substance, an error of as much as 1.6 per cent. of manganese would have been made.

These experiments, and a number of others of the same character that we have made in relation to the influence of

temperature, and of the different modes of heating mentioned in this paper, upon the precipitate of hydrated manganese dioxide formed by bromine and ammonia from solutions of manganous salts and upon manganoso carbonate, show—

1. That Mn_2O_3 is only formed from these substances by ignition for about an hour at almost a white heat in a gas muffle furnace, or other apparatus in which the Mn_2O_3 is protected from reducing gases.

2. That an ordinary red heat, such as is obtained over a Bunsen burner, is not sufficient to reduce the oxide to the state of Mn_2O_3 , and that an error of $\frac{1}{2}$ per cent. of manganese too much may be made in this way if the percentage of manganese is calculated on the assumption that the product obtained is Mn_2O_3 .

3. That there is a risk in all cases when the oxides are heated over a gas blow-pipe of obtaining an oxide containing less oxygen than Mn_2O_3 , probably due to the action of reducing gas permeating the heated platinum or entering the crucible under the lid, and that an error of as much as 3 per cent. of manganese too little may be made in this way.

4. Finally, that all determinations of manganese made by weighing the product, yielded by igniting manganoso carbonate or hydrated manganese dioxide in air, are unreliable unless the available oxygen in the product is also determined and taken into consideration.

Our investigations and experience have led us to the conclusion, that just as in the case of the estimation of iron, the volumetrical methods of estimating manganese are far superior to the gravimetrical methods, both as regards accuracy and ease of execution.

The volumetrical method described by one of us in 1879 (*Jour. Chem. Soc. Trans.* 1879, 365) with some modifications of detail, is still used by us. This method depends upon the whole of the manganese being precipitated as hydrated dioxide by calcium carbonate when chlorine or bromine is added to a solution of manganous salt containing also a persalt of iron or a salt of zinc, and under certain conditions of temperature, &c. We have reason to believe that this method is now adopted by many chemists both in private laboratories and in the laboratories of steel works, and we therefore think that the following description of it in its slightly modified form as we now use it for determining manganese in manganiferous iron ores, manganese ores, spiegeleisen, ferromanganese, &c., will not be out of place.

A quantity of the sample to be analysed, containing not more than about 4 grains (0.25 grm.) of manganese, is dissolved in hydrochloric acid. In the case of spiegeleisen and ferromanganese, about 50 grains (3-4 cc.) of nitric acid are afterwards added to oxidise the iron. In the case of manganese ores, ferromanganese, and manganese slags, which do not contain about as much iron as manganese, we add to the solution as much iron, in the form of ferric chloride, as will make the quantities of iron and manganese in the solution about equal. An excess of iron is no drawback, except that a larger precipitate has afterwards to be filtered and washed.

The excess of acid in the solution is then neutralised by the addition of calcium carbonate, which is added until a slight reddening of the solution is produced. The solution is then rendered very slightly acid by dropping into it just enough hydrochloric acid to remove the red colour.

We then add in all cases 1 oz. (30 cc.) of a solution of zinc chloride containing about 7 grains (0.5 grm.) of metallic zinc per ounce. The liquid is then brought to the boiling point, and diluted with boiling water to about 10 oz. (300 cc.).

Two oz. (60 cc.) of a solution of calcium hypochlorite, made by dissolving 1,500 grains of 35 per cent. bleaching powder in 100 oz. of water (about 33 grms. of bleaching powder per litre) and filtering, are then poured into the manganese solution; but we add to the hypochlorite solution, before pouring it into the manganese solution, just enough hydrochloric acid to give it a faint permanent greenish-yellow colour after gentle agitation.

The object of this addition of acid is to prevent a precipitate forming when the hypochlorite is added, due to the alkalinity of this solution. When hydrochloric acid is added in this way to the solution of calcium hypochlorite, the manganese solution remains clear on the addition of the calcium hypochlorite, and any possible local precipitation of manganese in a lower state of oxidation than MnO_2 is obviated.

Finally, we add to the manganese solution about 45 grains (3 grms.) of calcium carbonate diffused in about half an ounce (15 cc.) of boiling water. After the first evolution of carbonic acid has ceased, during which time the cover is kept on the beaker, the precipitate is stirred to make it collect together, and half a drachm (2 cc.) of methylated spirits of wine are added and it is again stirred.

The precipitate is then thrown upon a large filter of English filtering paper and washed, at first with cold water until the greater part of the chlorine is removed, and afterwards, to make the washing more rapid, with warm water at about 150° F. (65° C.). It is washed until, after draining, a drop shaken down straight from the precipitate, by gently jolting the funnel, shows no indication of chlorine when tested with a strip of iodised starch paper. As a matter of practice we always give two or three washings after there has ceased to be any indication of chlorine.

1,000 grains of an acidified solution of ferrous sulphate, containing about 10 grains of iron per 1,000 grains of the solution, and made by dissolving crystallised ferrous sulphate in a mixture of one part of monohydrated sulphuric acid and three parts of water, are then accurately measured off by a pipette and run into the beaker in which the precipitation was made. The precipitate, together with the filter paper, are then removed from the funnel and placed in the solution of ferrous sulphate in the beaker. The precipitate readily dissolves even in the cold (sometimes it may be

necessary to add a little more acid to dissolve the ferric hydrate completely), the manganese dioxide converting its equivalent of ferrous sulphate into ferric sulphate. A sufficient quantity of cold water is now added and the ferrous sulphate still remaining is titrated with a standard solution of potassium dichromate.

The exact amount of ferrous sulphate in 1,000 grains of the ferrous sulphate solution is determined by measuring off into a clean beaker another portion of 1,000 grains, and titrating with standard dichromate solution. The difference between the amounts of dichromate solution required gives the quantity of ferrous sulphate oxidised by the manganese dioxide, and from this the percentage of manganese in the sample can be calculated.

The ferrous sulphate solution should be standardised from day to day, as it undergoes slow oxidation on exposure to air.

By carrying out the process in the manner here described, the temperature of the liquid, immediately after the precipitation is complete, is about 170° F. (77° C.), and we find that the best and most constant results are obtained when the temperature after precipitation is near this point.

We have also tried the effect of precipitating the manganese with zinc oxide or calcined magnesia instead of calcium carbonate.

There are two objections to the use of zinc oxide. One of them is, that the presence of zinc in solution (due to the solution of the excess of zinc oxide in the acid of the ferrous solution) interferes with the titration of the excess of ferrous sulphate, by rendering the finishing point of the titration very indefinite. It has the property of delaying the formation of the blue colour that a ferrous salt gives with potassium ferricyanide, and the titration seems to be finished before the whole of the ferrous salt has been oxidised. Towards the end of the titration, whilst there is still some ferrous salt unoxidised, the drops taken out for testing show no colouration with the indicator until they have been mixed with it for several minutes, and unless patience and care are exercised it is quite easy to make an error of 1 per cent. too much manganese.

Another objection to the use of zinc oxide, and one that also applies to calcined magnesia, is that some oxidising chlorine compound is formed with these substances, which is very difficult to remove by washing, and which is retained in the precipitate after the washings have ceased to give any indications of chlorine with iodised starch paper. In one instance the zinc oxide method indicated 103 per cent. of manganese, and the magnesia method 100.75 per cent.

A solution of bromine in water may of course be used instead of the hypochlorite solution, in which case no acid is added to the bromine solution. When using bromine a solution containing about 10 grains of bromine per ounce (about 22 grms. per litre) should be used, and 3 oz. of this solution (90 cc.) used for precipitating about 4 grains of manganese.

The unpleasantness of working with bromine may be mitigated, to some extent, by adding to the bromine solution before pouring it into the liquid containing the manganese, a few drops of a solution of sodium hydrate until nearly all, but not quite all, the bromine is taken up. If an excess of sodium hydrate were added to the bromine it would produce a precipitate on pouring it into the manganese solution, and this is to be avoided.

We prefer to have both zinc and iron in solution with the manganese. When working with either of these alone we obtain all the manganese in the form of dioxide, but with iron alone there is a greater tendency to the formation of permanganate, than when zinc is also present. This point was also noticed by Wright and Menke (*Jour. Chem. Soc. Trans.* 1880, 43). When zinc alone is present we have found that the precipitation of the dioxide does not take place so rapidly as when iron is also present. When both iron and zinc are used, there is very seldom any permanganate formed, if care is taken not to use an unnecessarily large excess of chlorine or bromine, but occasionally there is a small quantity formed, especially if the precipitate is left to stand some considerable time before filtering. We have found that the addition of a very small quantity of alcohol immediately after the precipitation of the manganese

is complete, entirely prevents the formation of permanganate even when a large excess of chlorine has been used, and for this reason we make a practice of adding it.

It is known that the oxide precipitated by alcohol from a solution of potassium permanganate in water, is in a lower state of oxidation than MnO_2 , but by a long series of duplicate tests in which, to one portion of the sample, alcohol was added after precipitation, but before any permanganate had formed, whilst the second portion was, after precipitation, at once plunged into cold water and stirred until cold, thus effectually preventing any formation of permanganate, we established the fact that the alcohol had not the slightest reducing action upon the precipitate of manganese dioxide—in every case the duplicate tests were alike.

We find that when filtering paper has been wetted with the solution containing free chlorine or bromine and afterwards washed clean it has no reducing action either upon potassium dichromate or upon ferric sulphate. The addition of the filter together with the precipitate to the solution of ferrous sulphate therefore does not influence the result.

We must point out that the presence of lead, copper, nickel, cobalt, and chromium in the substances under examination interferes with the accuracy of this method of testing manganese. To what extent these substances respectively do so is seen from the following experiments, which were made with manganoso-manganic oxide of known composition. In each experiment the method of estimating manganese that we have just described was carried out, and the quantity of ferrous sulphate oxidised in each case was calculated into its equivalent of manganese. In the following table the results are given as parts of manganese indicated for every 100 parts of manganese actually present in the test.

Proportions taken.	Parts of Manganese indicated, per 100 Parts of Manganese taken.
100 parts Mn_2O_3 to 1 part Pb	100.23
100 parts Mn_2O_3 to 1 part Cu	100.23
100 parts Mn_2O_3 to 1 part Ni	100.23
100 parts Mn_2O_3 to 1 part Co	100.64
100 parts Mn_2O_3 to 1 part Cr	101.60

It will be seen that so large a proportion as 1 per cent. of lead, copper, and nickel has not greatly interfered with the test, but the interference of cobalt and, especially of chromium, is serious. All these substances, except chromium, form, under the conditions of the test, higher oxides insoluble in water, which are precipitated with the manganese dioxide, and which oxidise ferrous sulphate to ferric sulphate; whilst chromium forms some insoluble chromate which goes down with the manganese dioxide.

Fortunately these metals rarely, if ever, occur in the ores of manganese or in spiegeleisen and ferromanganese in sufficient quantity to effect the practical accuracy of this test.

This volumetric method cannot, however, be applied to the determination of manganese in alloys of these metals, such as ferro-chrome or in ores containing these metals, without previously separating them from the solution containing the manganese.

We have repeatedly tested this method of analysis with manganoso-manganic oxide of known composition, prepared as already described, and we have invariably obtained by it results indicating 100 per cent. of the manganese used in the test.

Mr. PATTINSON exhibited and demonstrated Lax's gas balance.

THE NOXIOUS VAPOURS OF MANURE WORKS.

BY JOHN MORRISON.

BEFORE the envelopment of chemical manure works within the powerful embrace of the "Alkali Works, &c. Act, 1881," the manufacture of superphosphates was carried on for the most part under simply dreadful conditions. Scarcely any serious attempt whatever was in many districts made to render matters agreeable either to the employes within or to the neighbourhood without the works, and had the dissolving process been continuous instead of intermittent, it is difficult to imagine how the men immediately engaged in it could long have survived its physically disastrous effects.

Some manufacturers, too, I am afraid, argued that inasmuch as the extra wages of the process workers liberally recognised the unwholesome nature of the occupation, they at least had no substantial cause of complaint. Also that as in most cases the towns had gravitated towards the works, rather than the works to the towns, the townspeople had little real grievance either.

Fortunately for humanity, however, the 1881 Act ushered in the longed-for dawn of a better day. Manufacturers unable or unwilling to conform to reasonable requirements judiciously and temperately enforced were gradually metamorphosed into merchants at probably little sacrifice beyond their own personal feelings; while of the rest, a notable proportion have readily constructed apparatus, not just barely sufficient to satisfy inspectorial requirements, but to thoroughly and completely prevent the discharge into the atmosphere of almost every particle of their acid vapour production.

The rapid development of the superphosphate industry, and the consequent increase of its nuisances, rendered of course the legislation of ten years back all the more imperative, for whereas with a trifling output, restricted to the close of each working day during the winter months, it was possible to carry on the process in hand tanks, and to utilise without serious inconvenience the entire works overnight as depositing chambers for the noxious exhalations, it is quite evident that the advent of large operations, mechanical mixers, closed dens, and gas draughting to the chimney, at once constituted the works enormous watering pots, from the spouts or chimney stalks of which the adjacent country was freely deluged with unwholesome vapours.

The noxious vapours, however, of the registered manure works, which are under the charge of and can be quantitatively determined by the Government inspectors, must be gearily distinguished from the powerfully offensive and searching stinks peculiar to the boiling of bones and treatment of blood, fish and flesh offal, &c. &c. in non-registered premises. These are wholly under the care of the local sanitary authorities, and with them I have at present of course nothing to do.

The stifling fumes evolved during the treatment of mineral phosphates with sulphuric acid consist chiefly of fluorine, carbonic, and sulphuric acids, intermingled with silicic tetrafluoride and much steam, and when these raw phosphates are treated in conjunction with animal matters various oily vapours of more or less unpleasant character are likewise produced.

There is no difficulty whatever about the arrest of these acid vapours, of which the fluorine acid is the chief. With sufficient time and space to react upon themselves, they will peacefully subside of their own accord. The sole difficulty lies in their arrest within reasonable space and limited time.

As calcic fluoride (CaF_2), fluorine occurs in most mineral phosphates, but in some, and those singularly the phosphates in largest present use, much more plentifully than in others. As hydrofluoric acid, the addition of sulphuric acid sets this fluorine free. Without silica at hand, the hydrofluoric acid escapes into the air. With silica present, fuming silicic tetrafluoride is formed. This also passes into the atmosphere, but only to be decomposed in presence of water into gelatinous silica and hydrofluosilicic acid.

The average in CaF_2 (or fluor spar) of South Carolina "River" phosphate and 40—45 per cent. Belgian phosphate, (which are phosphates very commonly employed for the production of the ordinary grades of mineral "supers") may be taken as not less than 3 to 3½ per cent., or, say, 70 lb. per ton; and as in the larger works 25 to 50 tons of phosphate are treated with sulphuric acid daily, it may be safely assumed that from 8 to 16 cwt. of hydrofluoric acid are regularly evolved during the very few hours out of the 24 which the dissolving operation each day usually occupies.

This implies that on the Tyne alone, in default of condensing plant, four or five tons of hydrofluoric acid would be discharged into the atmosphere every week. Such a fact was, in all conscience, sufficiently serious to demand the most earnest consideration, and the surprising thing was that it escaped legislative supervision so long.

I have given from time to time, since the passing of the Alkali, &c. Works Improvement Act, 1881, some little attention to the arrest of manure works vapours, having designed most of the apparatus in use for its accomplishment throughout the North of England. It may possibly, therefore, interest the members present to have the leading principles of the apparatus roughly described.

There is, however, no such appliance in existence as a "Morrison" tower, any more than a "Morrison" chimney or a "Morrison" sulphuric acid chamber, and my name has by various friendly writers been attached to apparatus for which I have been chiefly responsible, more, I assume, for convenience of reference than for any imagined originality either of principle or design.

There can be no doubt that the manure mixer fumes possess within themselves every element needed for their speedy destruction, and but a single element (heat) to in any way retard it. For this reason I am opposed to the introduction of steam advocated by many manufacturers, for it must be borne in mind that with every ton of superphosphate produced, at least 1 cwt. of water in the form of steam is evolved; and as such a quantity is quite sufficient to saturate the effluent gases, to introduce more is to provide what costs money and can be profitably dispensed with. Doubtless a steam jet will aid the draught, augment the agitation of the gases, and quickly purify up to a certain point an atmosphere thickly laden with noxious vapours; but it appears demonstrable that to the extent of the heat liberated in its own condensation, it must of necessity retard the perfect filtration of the residual vapours, and my impression is that any benefit accruing from its introduction is in any case wholly disproportionate either to its quantity or its expense.

The first desideratum is to cool the gases by draughtage into chambers or flues of sufficient area or length, and where this can economically be managed, little more is required; the fume will quietly subside of itself. But unfortunately it is too generally needful to accomplish a maximum of condensing work within a minimum of space, and where this necessity prevails, the only desirable alternative is to submit the gases to a sort of dry scrubbing process, so as to hasten the deposition of the fluorine compounds. I have managed this in such various ways as the special circumstances in each particular case permitted; but my invariable aim has been to provide, within a suitable flue, a sufficient number of impinging or baffling diaphragms by means of which the motion of the gases could be momentarily arrested and then diverted into another direction, for I have found that at such eddying points or contractions the greatest deposition of silica, &c. has taken place.

In this, then, the first stage of the process, the great bulk (say 90 per cent.) of the solid matter is arrested, so that the residual vapours chiefly now remain to be dealt with. These, therefore, I cause to traverse in an upward direction one or more water towers or wet scrubbers simply packed with wood spars, and after this treatment the gases are allowed to pass away to the chimney.

The necessary draught is created by means of an exhaust fan of special construction. This I find a convenient arrangement, for a well-balanced fan takes little power to drive, is noiseless, and is easily actuated by the mixer engine. It is best fixed between the towers and the chimney, and its power is controlled by a damper just

sufficiently to secure a slight "pull in" at the mixer mouth. The den doors are, of course, made as tight as possible, to avoid unnecessary dilution of the gases and interference with the efficiency of the fan.

Gas dilution means reduced condensing efficiency. For as beyond a certain point it is exceedingly difficult to scrub out the acid vapours, the augmentation by dilution with atmospheric air of gas bulks, increases of necessity the total acid escapes. It is the arrest of the last half per cent. which tries the mettle of the apparatus.

This is so exceedingly elementary as to be scarcely worth recapitulating. Yet there have been lots of failures, due to a total misapprehension of the necessities of the case and to the impracticable construction or wholly insufficient capacity of the condensing plant. For in the erection of the latter, two things have to be constantly borne in mind: one, that the evolution of the gas is spasmodic, and (especially in the case of hot vitriol) extremely violent when the spasm is on; and the other, that every chokable part of the apparatus must admit of the readiest possible access. To provide for the first of these, therefore, the plant has to be of ample dimensions, and unless the second be remembered, the most annoying failures at most inconvenient seasons are absolutely certain to ensue.

Where such failures involve stoppages and intervals of working discomfort, they are perfectly fatal to every semblance of manufacturing economy. For every unnecessary reduction in the day's dissolving tonnage, at a time so unremunerative as the present, is simply to add so many pence or shillings per ton to the manufacturing costs, and to sweep away, in all probability, every vestige of profit.

The wet scrubbers, as I have just said, are packed with wood spars. This is for two reasons: firstly, because (unlike coke packing) spars exert no thrust on the tower sides, and so save the necessity of tie-rods. And secondly, because they seem to afford a maximum of interstitial or scrubbing surface to a minimum of solidity. The firebrick packing sometimes adopted is, in my opinion, less economical, for not only does it largely augment the dead weight of the towers, but by its pigeon-hole overlap the ratio of useful surface to solid material is decreased.

I have been in the habit of making the spars of wedged section, as I think this shape delays the choking of the towers, both by affording extra space for the deposit of silica, and by facilitating its detachment and conveyance to the tower base by the action of the water. Silica deposited on the sides of square-sectioned spars clogs the tower by reducing the packing spaces. But on wedged-section spars a considerable deposit can take place without affecting the packing mesh at all.

I usually advocate—where economy of water is an object—one tall tower, in preference to two or three shorter ones. But the prevailing arrangement is a tower of moderate height, divided into two packed upcasts, with a downcast flue between.

These arrangements, of course, do not specifically deal with the arrest of organic matter, which, in the early days of the 1881 Act, the Government inspectors urged manufacturers to destroy by passage of the final gases over a boiler fire. But there is no need for any such complication, as in a properly equipped apparatus the great bulk of the organic matter is carried away in the scrubbing water, and the effluent gases even discharged (instead of through the usual chimney) directly into the atmosphere, exert no appreciable nuisance.

Besides, what is the good of a passage over a boiler fire? Its only possible effects would be dilution without destruction, and reduction of the boiler efficiency. The destruction of organic matters, in fact, by any such means is a sheer impossibility. You can no more burn them by racing the gases impregnated with them over a fire than you can similarly burn smoke. To talk about burning smoke is, of course—practically speaking—to talk nonsense, and the only sensible talk relates to its prevention. Once produced, it, of necessity, goes to the chimney.

To successfully burn the organic matters in manure gases, the entire volume of the latter would have to be raised to the ignition point of the former. And this would involve combustion by passage through a fire: a special and an

expensive arrangement. Of course, the fine requisite for such ignition and destruction might be utilised for the creation of the draught required for the exhaustion of the gases through the scrubbing apparatus, but such an arrangement would be so incomparably more troublesome, inefficient, and costly than a fan, as to be utterly unworthy of the serious attention of any practical man.

But in speaking of the organic matters of chemical manure works, I may mention that it always seems to me a pity that they are not properly included in the 1883 Act. At the present moment, I presume, the Government inspectors have merely a sort of complimentary control over other than the acid vapours in dissolving gases, and that they have no power of legal action regarding the discharge into the atmosphere of organic matters from the mixing machine, however offensive; yet in my opinion, if manure manufacturing is to be controlled at all, it ought to be controlled fully and comprehensively. From a manufacturer's point of view I consider it infinitely better to be wholly under a dignified and a scientific Government supervision than to be periodically bullied and browbeaten by the uninformed nuisance-inspecting fumbles of the sanitary authorities; and, so far as I can see, there is nothing to prevent the incorporation within the 1881 Act of every process, whether chemical or mechanical, dealing with products used in agriculture, and the enforcement in connexion therewith of the use of the best possible means to obviate nuisance.

It may, of course, be argued that it is rather difficult to define a nuisance which cannot be dealt with quantitatively by any ordinary analytical methods; that what may to one man be a delightful perfume, may to another be a disgusting stench; and that where odours are chiefly of an empyreumatic character, it is not easy to discriminate between what is positively injurious to health and what is merely offensive to the nostrils of a super-sensitive "British public." Still there is a large margin which might safely be legislated upon; and, while the transfer to and storage in non-manufacturing premises might safely continue in the hands of the local sanitary authorities, I for one hope that both the storage and treatment within registered manure works, of every kind of animal or fish offal liable to putrefaction, may speedily be placed under the immediate control of Mr. Fletcher and his assistants.

DISCUSSION.

In answer to a question Mr. Morrison said that the length of time between the mixers and the scrubbers was dependent on circumstances, but that he preferred a length of 200 feet. The dimensions also would vary with the amount of work done; for a decomposition of 20 to 30 tons per week, a diameter of 18 inches would be about sufficient.

Mr. W. S. Connor referred to the destruction of noxious matters of animal origin. He had had to deal with the products of decomposition of fish, and thought he had completely got over the difficulty. His plan was to draw the gases from closed vessels by a fan, which then drives them up a tower where they are exposed to a shower of water, and down a second tower. They are then brought under the lens of the boiler fire, through which they pass to the chimney. At the top of the chimney no odour can be detected.

ON THE DETERMINATION OF CHROMIUM IN STEEL.

BY T. W. HOGG.

ALTHOUGH chrome steel has been known since 1820, it is only within the last few years that it has attracted much attention. When chromium is added to steel to the extent of from 0.5 per cent. to 4 per cent., the alloy is found to possess a greatly increased tensile strength, and such steels may be so treated that extreme hardness is produced without the great tendency to fracture which exists in other hard steels; and it is considered by many metallurgists that the addition of even small quantities of chromium improves the ordinary and better classes of carbon steels.

It is however most likely due to the fact that the preparation and methods of using these steels demand so much more than ordinary care and skill that they have not been more largely introduced.

The principal object of this short paper is to describe a simple method for determining the chromium in these alloys, but as it is of great importance that the analyst should be in the possession of both accurate and rapid methods, perhaps the few following remarks upon the two methods now in use may be of interest.

Galbraith's process (Chem. News, 1877) is the only rapid one we have; it consists in dissolving a weighed portion of the steel in dilute sulphuric acid (1 to 6), and then an excess of permanganate of potassium is added, either in solution or crystals, and then the liquid is boiled until all the manganese is precipitated; the liquid is now filtered and the chromic acid in the filtrate ascertained by adding an excess of ammonio-ferrous sulphate and titrating with standard bichromate.

It has been objected that the whole of the chromium is not dissolved by the sulphuric acid; this objection most likely has arisen from insufficient boiling with the strength of acid originally given; only the merest traces of chromium escape solution if a stronger acid is used, namely, 1 to 3, and if boiling is kept up vigorously for a few minutes after all decomposition has apparently taken place. Another probable source of error arises from filtering the liquid through filter paper; if this is done a small quantity of chromic acid will be reduced, and if the solution is concentrated and hot, and the filtration at all slow, which sometimes happens, the error from this cause alone may become serious; for this purpose an asbestos filter only should be used.

Again, in order that the precipitation of the manganese be effected as rapidly as possible, the liquid should not be diluted any more than can be helped; the crystals, or better still, the finely powdered permanganate, should therefore be used and not the solution. If very prolonged boiling is ever necessary to precipitate the manganese, the results are sure to be too low.

With these precautions reliable results may be obtained, and if duplicate determinations be made, using different quantities of the steel, there is not much fear of going astray.

With regard to the gravimetric method, it has been variously recommended to precipitate the mixed metals after the steel has been decomposed either as sulphides, oxides, or carbonates, with subsequent filtering and drying; a better method is to evaporate the solution of the steel in hydrochloric acid down to dryness, as recommended by F. O. Arnold (Chem. News, 1880); after mixing and igniting gently with an excess of sodium carbonate, potassium hydrate is added and heat applied. As soon as the mass is in a state of fusion, potassic nitrate is gradually introduced in small portions at a time until the decomposition is judged to be complete; this operation is best conducted in a capacious nickel crucible. The presence of the potassic hydrate enables the operation to be conducted at a much lower temperature; in fact, the crucible may be heated quite sufficiently upon a gauze. Nickel crucibles answer well for this work; moreover the direct contact of the flame is not needed, they do not get such an abundant carbonaceous deposit upon them. The

fusion is then treated with water, and if any manganese is suspected to have passed into solution a drop or two of alcohol is added, and the liquid allowed to stand for a while before filtering. The filtrate is concentrated somewhat and acidified with hydrochloric acid. As a rule there is sufficient potassic nitrite present to ensure the complete reduction of the chromic acid, but in case there is any doubt a little more acid is added, and then two or three drops of pure alcohol. After warming gently, dilute ammonia is added in slight excess as soon as the liquid has attained the right colour. Prolonged boiling before adding the ammonia often produces some change in the condition of the chromium whereby its complete precipitation is rendered very difficult. These chromium chloride solutions are very capricious with regard to their precipitation, and occasionally a pinkish solution is obtained; this as a rule will disappear upon heating gently for some time, or if a few drops of hydrochloric acid be added, again precipitating by ammonia; if the quantity of chromium present is very small, it is best to add ammonium sulphide and allow to stand over night.

I may here mention that nitric acid and alcohol reduces chromic acid solutions much more quickly than hydrochloric or sulphuric acid and alcohol; a very small quantity of alcohol is sufficient for the purpose.

After the precipitate has completely subsided, it is washed thoroughly, ignited, and weighed, then placed in a small beaker, treated with strong nitric acid and chlorate of potash, and warmed very gently; after the residue appears to be free from chromium, water is added and then a slight excess of ammonia. After standing a short time the precipitate is filtered off and washed. A few drops of nitric acid are poured over the filter, which is washed, and ammonia again added to the solution. This is done to separate the little chromic acid which is always carried down by the precipitate. The precipitate is rinsed on to the same filter, washed, ignited and weighed; this weight deducted from the first one gives the weight of pure chromic oxide, if this is only present in small quantity it should be again precipitated from the filtrate and weighed directly. By this treatment there is separated from the impure chromic oxide silica, alumina, and phosphoric acid. It is probable that many determinations of chromium are extremely faulty, especially when this element is only present in small quantities, on account of other impurities than silica. Fresenius states that lime is also occasionally present, but I have never detected any.

This method, of course, cannot be used where the results are wanted in a short time, and no doubt it requires much more patience and skill than the volumetric one.

I will now draw your attention to the following very rapid colorimetric method. Every one who has had experience with chrome steel knows that the solution of the steel in sulphuric acid is highly coloured, the intensity of the colouration being greater as the percentage of chromium increases. Sulphate of iron itself, of course, possesses a green tinge, but the colour intensity of chromium sulphate is so vastly greater than that of ferrous sulphate that the presence of such a small quantity of chromium as 0.1 per cent. is sufficient to give a decided increase to the colour intensity of the solution, and the presence of 0.35 per cent. will almost double it. So far as I have been able to ascertain, this simple fact does not appear to have been applied by anyone for the purpose of determining the quantity of chromium present.

Experiments with chrome steels in which the chromium had been carefully determined by the gravimetric method when compared with the colorimetric one gave very concordant results. I need hardly mention that it is necessary to have accurately-prepared standard chrome steels, the nearer they are to the steels to be examined the better, but a 2 per cent. standard may be used for all steels between 1 and 4 per cent. For steels of lower percentages down to 0.3 per cent. it is necessary to have other standards, but an approximate result useful for many purposes may be obtained from a 1 per cent. standard if careful corrections be applied for the colour value of the iron itself. The method is as follows:—Take 0.2 grm. of the steel of the standard, and also of pure iron, dissolve each in 5 cc. of dilute sulphuric acid (1 to 3), using a rather wider tube

than is usual for the Eggertz colour testing, for if the tube is narrow the steel is partially carried up and deposited upon the sides. The decomposition is hastened by placing the tubes upon a hot plate or by heating in a water-bath, they are then boiled over the lamp for a couple of minutes, and then cooled and filtered. The solutions are now compared and their colour intensities adjusted. There are so many different ways of doing this that I need not describe in detail any of them. I myself prefer to use graduated flat-bottomed tubes about half an inch in diameter, comparing the solutions by looking down through them as they are held over a mirror so placed that the light is reflected vertically. The pure iron is also examined and its value in terms of the standard ascertained; once known it need not be done again. From this a table of corrections is prepared, bearing in mind that the quantity to be deducted or added gradually decreases as the steel approaches the standard in value; the quantity to be allowed when these are approximately equal to each other is so small that it may be neglected.

DISCUSSION.

The CHAIRMAN referred to Mr. Hogg's remark on the reducing action of the filter paper on chromic acid compounds. He said he had found the same trouble in dealing with compounds of manganese, but had got over it completely by first submitting the filter to the action of a solution containing chlorine, bromine, or bleaching powder, afterwards washing with ammonia. Paper so treated was found to be without reducing action on chromic or manganic compounds.

June 1st (Glasgow):—

- Dr. E. J. Mills. "Destructive Distillation." Part II.

Meeting held at the Societies' Rooms, 297, Bath Street, Glasgow, on Monday, April 6th, 1891.

MR. E. C. C. STANFORD IN THE CHAIR.

THE DETERMINATION OF IMPURITIES IN PARAFFIN SCALE, &c.

By J. STUART THOMSON.

Despite several attempts to formulate a uniform scheme for the analysis of paraffin scale, differences between buyer and seller are still of not unfrequent occurrence, and as it is now generally acknowledged that the cause of such differences arises largely, if not indeed entirely, from the use of varying methods of testing, the Scottish Mineral Oil Association (a body composed of representatives of the mineral oil companies in Scotland), with a view of securing greater uniformity in results, passed the following resolution at a meeting held on 11th June 1890:—

"DETERMINATION OF IMPURITIES IN SCALE AND FLASHING POINT OF HEAVY MINERAL OIL."

"Mr. Fyfe referred to correspondence he had had with Mr. Calderwood (Price's Company) on this subject, and suggested that the chief chemist of each company should meet together, and consider the questions at issue, with a view of formulating a mode of determination which would be applicable to all. Mr. Thomson (Young's Company) to be convener. This was unanimously agreed to."

The committee thus appointed consisted of the following members:—

- Mr. E. M. Bailey, Pumphreyston Oil Company, Limited.
- Mr. Fred. Bishop, Linlithgow Oil Company, Limited.
- Mr. R. Dunlop, Stanrig Oil Company.
- Mr. John Gray, Clippens Oil Company, Limited.
- Mr. J. Moffat Johnston, Oakbank Oil Company, Limited.
- Mr. T. R. Sandeman, West Lothian Oil Company, Limited.
- Mr. J. Spencer, Burntisland Oil Company, Limited.
- Mr. D. R. Stewart, Broxburn Oil Company, Limited.
- Mr. W. B. Syme, Young's Oil Company, Limited (Addiswell).
- Mr. J. S. Thomson, Young's Oil Company, Limited (Claphall).

who after holding several meetings and making a large number of experiments, ultimately drew up a scheme, giving a description of what they considered to be the best means for determining the impurities in paraffin scale, &c. This scheme was then submitted to Mr. Calderwood and Mr. Boverton Redwood, as representing certain of the buyers, and after correspondence regarding some points on which there was a difference of opinion, it was finally adjusted, and has been accepted as the recognised method for the analysis of scale, &c.

It was thought that not only should such a scheme be made as widely known as possible, but also that some explanation and reason should be given, as to the grounds which led to the adoption of the particular processes. As convener of the committee, I was asked by the members to do this, by means of a communication to be laid before this Society. In carrying out this request, I have dealt with each paragraph in the order given in the scheme, which appears as an appendix to this paper. As this point it may be convenient to point out that the literature on the subject of scale-testing is extremely meagre, nearly all

published facts of importance being found in one or other of the following papers:—

Boverton Redwood—*Jour. Soc. Chem. Ind.*, Vol. III., page 430.

Boverton Redwood—*Jour. Soc. Arts.* 1886, Cantor Lectures, page 56.

D. A. Sutherland—*Jour. Soc. Chem. Ind.*, Vol. VI., pages 123 and 271.

I. SCALE ANALYSIS.

"Scale," it may be explained, is the trade term for crude solid paraffin: it receives this name from the fact that it consists principally of masses of flat crystalline plates or "scales" of the higher members of the paraffin series (C_nH_{2n+2}) of hydrocarbons. In commercial scale there is present, in addition to the solid hydrocarbons, varying quantities of oil, water, and mechanical impurity or dirt, and as these if present in excess are valueless, if not indeed deleterious, it is necessary to estimate their amount. It should be pointed out that there is no sharp line of demarcation between the solid hydrocarbons and the oil, these passing gradually through "soft" or low melting paraffins into each other, and there is no doubt but that a portion at least of such soft paraffins are expressed along with the oil and estimated as such. It will thus be seen that the test for oil is a purely arbitrary one, and consequently the most careful attention must be given to the specified details when carrying it out. In "hard" scale the normal amount of impurities accepted by the trade is 6 per cent, made up of 1 per cent. oil and 2 per cent. water and dirt, everything in excess of these being deducted from the gross weight of the scale.

1. Sampling Scale.

Experience has shown that unless great care be taken in the sampling of scale very discordant results may be obtained; by the use, however, of a conical metallic tube such as is described in the schedule, a perfectly representative sample of the cask, waggon, or bing may be readily obtained.

2. Preservation of the Sample.

It was found by Mr. McArthur (Price's Company), as well as by members of the committee, that unless precautions were taken, samples of scale rapidly lost water when exposed to the atmosphere, consequently the directions given in paragraph 2 were inserted to prevent this so far as possible. Further, unless the bottles are completely filled, the water present is liable to separate and condense in the upper part, thus tending to render the sample non-homogeneous. In fact the analysis of a scale should be proceeded with as soon as possible after sampling.

3. Determination of Oil in Scale.

Before dealing with the sub-chapters of this section it may be explained that the principle on which the determination of oil in scale is based is to subject a given quantity of the scale, suitably prepared, to a definite pressure, for a given time, at a specified temperature, and observe the loss in weight which it sustains.

(a.) *Description of Press to be used.*—The first form of press used for this purpose, in Scotland at least, consisted of a simple powerful screw, operated by a long lever; this was and is still known as the "Walls" press, and its only drawback is that it was not furnished with any means for indicating the pressure applied, which is perhaps the most important requirement in a press for treating scale. Of presses capable of indicating the pressure, several forms were brought under the notice of the committee, a short description of which may not be without interest.

1st. Those, in which the pressure is applied by means of weights hung at the end of either a single long lever or a system of multiplying levers; the pressure being calculated from the length of the lever or levers, and the weights

applied. Such a form of process is thus similar in principle to the machines used for testing the strength of metals, cement, &c. A press of this type is used by Mr. Boverton Redwood. (Fig. 1.)

Fig. 1.

2nd. Those, in which the power is obtained by means of a screw and long lever, the pressure being indicated by the amount of compression of a powerful spiral steel spring. This form, which is in use in several of the Scottish oil works, was designed by Mr. Wm. McCutcheon, by whose name it is frequently known. (Fig. 2.)

Fig. 2.—ELEVATION.

Fig. 2.—PLAN.

Fig. 3.

3rd. Those, in which the power is also obtained by means of a screw and lever, but the amount of pressure applied is indicated by the deflection of a powerful flat steel spring, which constitutes the cross-head of the press: the slight deflection of the spring being magnified by a lever indicator. This form of press is also made use of by Mr. Boverton Redwood. (Fig. 3.)

4th. Those, which are in reality miniature hydraulic presses: the pressure being indicated by means of an ordinary

Fig. 1.

Bourdon gauge. Messrs. Clarkson and Beckett, engineers, Maryhill, Glasgow, some years ago introduced a very neat press of this description, which has been highly spoken of.

The question of what form of press should be recommended was one which was very fully considered by the committee; ultimately, however, they agreed that any form of press which had an arrangement for indicating the pressure might be employed provided the cup in which the scale was placed had an area of 20 square inches.

(b.) *Preparation of the Sample.*—This is a most important detail, and one which must be most carefully attended to. The first step is to free a portion of the sample from the water and dirt present; this is done by melting at a gentle heat and subsidence, the reason for so doing being that if the water were allowed to remain a varying proportion of it would be expressed along with the oil, when the sample was subjected to pressure. The melted scale is then allowed to cool slowly overnight to a temperature of 60° F., the object of the slow cooling being to allow of the scale crystallising in as large crystals as possible, it having been found that the result of suddenly cooling scale is a mass which is amorphous or nearly so, and which does not part with its oil so readily as scale which has been slowly cooled. The most preferable means of cooling scale is to float the basin or vessel containing the melted scale on the surface of a comparatively large volume of hot water, thus ensuring that the solidification takes place as slowly as possible. After cooling, the sample is ground to a fine powder, either in a mortar or by means of a small mincing machine, when it is ready for use. At one time it was not unusual to mould the scale into a thin round cake of about the required weight, and use this without further preparation for the determination of the oil. Such a procedure is now, however, entirely given up, as it was found to be not only more troublesome, but less accurate, than the method just described, owing to a portion of the oil adhering to the sides of the mould.

(c.) *Quantity of Scale to be used.*—At the first meeting of the committee a number of the members were of opinion that 250 grains of scale, the quantity hitherto employed for the determination of oil, was too large; as, especially with scales containing an excess of oil, when this quantity was used, the paraffin was liable to exude beyond the press cloths. This was acknowledged by all, but as doubts were expressed as to the effect of reducing the quantity, it was arranged that Mr. Moffat Johnston and myself should each prepare a sample of scale, portions of which should be sent to each member, who would then experiment thereon, using quantities varying from 150 to 250 grains. Of the two samples, the one contained over 7 per cent. and the other about 3 per cent. of oil. The numerous results thus got were tabulated, and an average taken, from which the following figures are obtained:—

Quantity of Scale employed.	Percentage of Oil found.	
	No. 1 Sample.	No. 2 Sample.
Grains.	Per Cent.	Per Cent.
150	7.78	2.98
250	7.56	2.83

Although these results show that an appreciably greater loss occurs when the smaller quantity is employed, the majority of the members of committee, after considerable discussion, resolved to recommend that the smaller quantity should be adopted. To this, however, the London chemists objected, stating:—

"With hard Scotch scales, using 250 grains we do not experience the difficulty of the paraffin spreading beyond the cloths. With soft scale this sometimes happens."

On this ground, therefore, the original recommendation was modified, so that while 250 grains are still to be used with ordinary "dry" scales, the quantity is to be reduced to 150 grains if the scale contain an excess of oil (over 7 per cent.) or if it be of low melting point (soft scale).

(d.) *Temperature at which the Scale is to be Pressed.*—This was fixed at 60° F. as being the temperature in universal use. The important influence which even slight variations of temperature have upon the results, has already been pointed out by Mr. Redwood in the paper referred to, so that it is unnecessary to further direct attention to the importance of this detail.

(e.) *Time which the Scale is to Remain under Pressure.*—While some members were of opinion that in some cases at least it might be advisable to press in two stages, applying fresh absorbing papers at each, it was ultimately decided to fix the time at 15 minutes, allowing the sample to remain in the press for the whole period.

(f.) *Pressing Cloths and Papers.*—The object in the use of these is the absorption of the oil which exudes from the scale when it is subjected to pressure, and in order that they may do this efficiently, certain small precautions should be carefully attended to.

The cloths between which the scale is placed are cut from fine linen, which should be thoroughly washed previous to use to remove the starch or dressing which is usually present, and which if allowed to remain tends to prevent the free passage of the oil. For the same reason the cloths should be perfectly dry when used.

The papers which act as the principal absorbents of the oil are usually cut out of ordinary blotting or thick filter paper; any fairly thick bibulous paper giving satisfactory results; like the pressing cloths the papers should also be thoroughly dried before being used. In regard to the number of layers of paper necessary to ensure complete absorption of the oil, this varies with the amount of oil present in the scale; never less than six ply of paper on each side of the cloths should, however, be used, and this number will be found to be sufficient with scale containing 4 per cent. of oil. Should the oil exceed this amount, the number of papers must be increased, so that the exterior papers are not soiled by oil, thus ensuring that an excess of absorbent material is present.

In the printed directions no particulars are given as to the manner in which the pressed cake is to be weighed, and on this point it is possible that some little difficulty may arise which will call for future adjustment. In many of the Scotch oil works it is the custom to employ pressing cloths which have been previously saturated with scale, *i.e.*, cloths which have been in use for some time, and to weigh the pressed cake of paraffin along with the cloths. Mr. Redwood, on the contrary, informs me that he is in the habit of using fresh or clean cloths for every test, and of weighing the pressed cake bare or without the cloths. A good deal might be said in favour of each of these methods, and with a view of determining if they had much effect upon the ultimate result, Mr. Moffat Johnston and Mr. Syme have kindly, at my request, made a number of experiments on the two methods; their results, together with those of a similar set of experiments made by myself, are given in the following table:—

TABLE.

EXPERIMENTS ON THE DETERMINATION OF OIL IN SCALE, using (1) Fresh cloths for each determination; and (2) cloths which had previously been saturated with scale under the maximum working pressure of nine tons, and weighing the pressed cake both with and without the pressing cloths.

Observer.	Cloths.	Percentage of Oil found.	
		Weighed with Cloths.	Weighed without Cloths.
J. M. J.	Fresh	1'94, 1'88	3'51, 3'66
W. B. S.	Fresh	2'74, 2'70, 2'76, 2'77
J. S. T.	Fresh	1'86, 1'98, 2'00	2'84, 2'80, 3'08, 2'88
J. M. J.	Saturated	2'81, 2'87	2'85, 2'70
W. B. S.	Saturated	2'28, 2'31, 2'34	2'35, 2'30, 2'28, 2'34
J. S. T.	Saturated	2'74, 2'80	2'52, 2'64

Note.—Mr. Syme's results are somewhat lower than either Mr. Johnston's or my own, but this is accounted for by the temperature of his press being 57° F. in place of 60°.

These results go to show that, with comparatively dry scales at least, the use of fresh cloths for each test and weighing the pressed cake by itself gives results higher by about 0.5 per cent. than those got when using saturated cloths and weighing the cake along with the cloths. This slightly higher result I attribute to two causes, 1st, the difficulty of completely separating the paraffin from the cloths; and, 2nd, the cloths themselves absorbing a portion of the scale. In the case of a purely arbitrary test such as this is, it is scarcely possible to decide which of the two methods is the more accurate; but seeing that the difference is in reality so small, scarcely indeed exceeding the limits of the error of manipulation, it is perhaps immaterial which process is employed.

I may here add that I have recently adopted a steel punch for cutting out the pressing cloths and papers, as was recommended by Mr. Redwood, and can corroborate his statement as to its usefulness.

(g.) *Pressure to be applied.*—The amount fixed is that in almost universal use, and which has been found to give results in conformity with manufacturing operations. Some of the English chemists were inclined to reduce the maximum pressure to 8 cwt. and the working pressure to 7 cwt. per square inch; this was not however pushed and the pressure was allowed to remain at 9 and 10 cwt. respectively. It should be pointed out, that slight variations in pressure have not anything like the effect on the results that small variations of temperature have.

With "soft" or low melting point scales the pressure fixed would be much too high; but as crude soft scales are not, except upon very rare occasions, to be met with in commerce, the committee did not consider it necessary to lay down any regulations regarding the testing of them.

4. Determination of Water in Scale.

Of the various matters which came under the consideration of the committee, there was none which gave rise to a more interesting discussion than this, the determination of water in scale.

The numerous processes which have been proposed for this purpose may be conveniently classed under two heads, *viz.*:—

1st. The "subsidence" methods, that is those where a given quantity of scale is melted, and the quantity of water which settles down to the bottom of the vessel measured or weighed.

2nd. The "evaporation" methods, that is those in which the water is driven off from the scale by heat, the amount being determined either by condensing and measuring, or by the loss in weight which the sample sustains.

A full description of the "subsidence" methods being found in Mr. Sutherland's paper, it is unnecessary to refer again to them here.

Of the "evaporation" methods, three modifications, *viz.*, distillation from a copper flask, Price's Company's method, and distillation from a small Erlenmeyer flask, were brought under the notice of the members; the first two of these are described in detail in the Appendix, the following being a description of the third:—

Distillation from a small Erlenmeyer Flask.—From 300 to 500 grains of the scale are placed in a small tared Erlenmeyer or conical glass flask, about 5 inches in height, to which a short glass conductor tube, bent at a slight angle, is attached by means of a well-fitting cork. It is then placed on a small shallow sand-bath, covered with a suitable conical tin shield and the whole slowly heated. On heating the water is volatilised, the greater portion being condensed in the conductor tube, at the end of which it is advisable to place a small porcelain basin. In about 15 to 20 minutes practically all the water will have distilled over, this being known by the cessation of "crackling;" the cork is now removed and the flask placed in a steam-bath for a few minutes to allow of any small traces of moisture adhering to the neck of the flask to evaporate; it is then allowed to cool and again weighed, the loss in weight being taken as water.

Regarding these various processes, it may be pointed out that when employing the first method, that with scales containing but a very small percentage of water, it is sometimes difficult to remove the last traces of water from the condenser tube, and consequently in such cases the results are liable to be slightly (about 0.3 per cent.) too low. The reason for the insertion of the last clause in the description of the second method was that it had been found that a certain quantity of oil was volatilised along with the water, and the second experiment with scale freed of water is made with a view of determining the amount so lost. The London chemists were of opinion that such an experiment was unnecessary in every case, and that all that was requisite was to determine the loss once for all for a given class of scale. With the third method the results are liable to be slightly in excess of the actual amount of water present, owing to small quantities of solid paraffin and light oil being volatilised along with the water, but if thought necessary a correction can be applied in a similar way to that described under the second method.

The members of committee were unanimously of opinion that none of the "subsidence" methods were sufficiently accurate to warrant their adoption, and in this the English chemists were at one with them. They were thus left with the three "evaporation" methods, and in order to decide as to the relative merits of each, it was arranged that the members should carry out experiments on the samples of scale prepared by Mr. Johnston and myself. Owing to the fact that, when these samples were distributed, the rapidity with which scale lost water unless most carefully packed, was not thoroughly realised, the results of the various observers are unfortunately not comparable with each other. However, the results obtained by each member showed that in point of accuracy all the three processes were on a par. This being so, the committee decided to select two of them, the result being that the first and second methods were adopted.

The majority of the members of the committee appeared to prefer the distillation from a copper flask; it has, however, the disadvantage of requiring at least 1 lb. of scale to operate on, and this quantity is not available in every instance. At the same time the method is a most convenient one for the regular testing of the daily make of scale in the works, as it practically requires no attention after being once started. Mr. Calderwood and Mr. Redwood, while acknowledging that both processes were equally accurate, expressed a preference for the second method, considering it to be the one most easily manipulated. There is, however, but little doubt but that the preference in each case arises largely from custom and habit.

5. *Determination of Dirt in Scale.*

Regarding this, it is merely necessary to state that in ordinary Scotch scale the percentage of dirt rarely exceeds 0.2 per cent., and it consists chiefly of vegetable fibre derived from the cloths in which the crude scale is pressed, and of oxide of iron from the condenser worms, &c.

6. *Calculation of the Results of the Analysis of Scale.*

No remarks appear to be called for upon this point.

7. *Determination of the Melting (Setting) Point of Solid Paraffin.*

The method specified was not under the consideration of the present committee, it having been adopted some time previously by representatives of the buyers and sellers; it was, however, thought advisable to incorporate it in the present set of directions.

Commercial scale, as already stated, consists of a mixture of the higher numbers of the paraffin series, and it has been found that the "English" test gives more certain results with such a mixture than the capillary tube. The point taken as the "melting" point is, more correctly speaking, the "setting" or "solidifying" point, in the case of paraffin, the real or actual melting point being some 2 to 3 °F. higher.

III. FLASHING POINTS OF HEAVY MINERAL OILS.

8. *Determination of the Flashing Point of Heavy Mineral Oils.*

The use of the covered oil cup of the "Abel" or Government flash-point apparatus for burning oils has gradually become general for the purpose of determining the flash-point of heavy or lubricating oils as well. Its use for this purpose is, however, attended with one rather serious drawback, which is, that when used for high temperatures there is no arrangement for regulating the rate at which the oil is heated. When the Abel cup is used for heavy oils, it is usually heated by means of a small naked flame or on a sand bath, and with a view of making the rate of heating as regular and uniform as possible, the committee specified that not less than 15 minutes should be taken in raising the temperature of the oil to 300 °F.; when this is done, fairly concordant results are obtainable.

When the committee first met, Mr. Calderwood brought under their notice a German apparatus, designed by Pensky and Marten,* which he reported as yielding most satisfactory results, both in Mr. Redwood's hands and his own. A short description of this apparatus is to be found in this Journal, 8, 734, and the principal feature which distinguishes it from the Abel arrangement is, that it is provided with a stirrer, which ensures not only a thorough agitation of the oil, but also of the air or vapour above the oil.

Experiments showed that the discrepancies which frequently occurred with the old method, arose from local overheating of the oil as much as anything else, and that when a stirring arrangement is attached to the oil cup to prevent this, the rate of heating within wide limits was practically without effect upon the result. In these circumstances it was, therefore, specified that in the event of

a dispute arising as to the correct flashing-point of a heavy mineral oil, it was to be decided by means of the Pensky-Marten apparatus.

III.—VISCOSITY OF MINERAL OIL.

9. *Determination of the Viscosity of Mineral Oil.*

The whole question of the determination of the viscosity of mineral and other oils has already been so fully dealt with by Mr. Boyerton Redwood (this Journal, 5, 121), that it is unnecessary to add anything further here; in fact, the method now adopted is practically identical with that which is therein recommended.

IV.—SETTING POINT OF MINERAL OIL.

10. *Determination of the Setting Point of Mineral Oil.*

The setting point of a mineral oil is unfortunately a term to which the most diverse definitions have been applied, some taking the setting point as the temperature at which a given volume of the oil ceases to be fluid, while others again consider the setting point to be the temperature at which an oil just commences to deposit solid matter (paraffin). The latter definition is the one most generally understood among buyers and sellers of Scotch mineral oils, but even here, owing to slight variations in the manner of manipulation, differences of several degrees (Fahrenheit) are not uncommon. In these circumstances the committee framed the directions given in paragraph 10 of the schedule, believing that if the various details be carefully followed, concordant results will be readily obtained by different observers.

When this description of the method for determining setting points was submitted to Mr. Redwood, he took exception to it, stating "This is a method which is only applicable in the case of certain oils and is therefore unsuitable for general adoption," and on making further inquiry as to what oils he had found the process unsuitable for, he again wrote: "According to my experience, the test you propose cannot be advantageously applied in the case of some pale American oils of high viscosity, the solid hydrocarbons in which more nearly resemble vaseline than paraffin."

In addition to such American oils, the proposed process is also inapplicable to Russian heavy oils, which have no true setting point. As however the present rules only apply to Scotch mineral oils, the directions were allowed to stand as originally drafted.

In bringing this paper to a conclusion, I have on behalf of my colleagues and myself to express our thanks to Mr. Calderwood and Mr. Boyerton Redwood for much valuable information and assistance, and to Mr. McArthur, chemist to Price's Company, for numerous analyses and tests, and also for their kindness in granting permission to make use of the same in the drawing up this paper.

APPENDIX.

METHODS OF DETERMINATION AS TO SCOTCH SCALE AND HEAVY MINERAL OILS, agreed upon by the chief Chemists of the SCOTCH MINERAL OIL ASSOCIATION, and certain Representative Purchasers.

I.—SCALE ANALYSIS.

1. *Sampling of Hard Scale.*

The sample is to be taken by means of a metal tube, which is made slightly conical; the small end is inserted in the scale, and by means of a handle, which is removable, it is forced through the scale to be sampled. By this means a cylindrical core of paraffin is obtained.

Care must be taken to see that the tube is of such a length that the sample will represent the whole length or depth of the cask, waggon, or bing.

* To be obtained from Sommer and Rinow, Wilhelmstrasse 122, Berlin.

2. Preservation of Samples of Scale.

Immediately after the sample has been drawn it is to be thoroughly mixed, placed in suitable wide-mouthed bottles, which may be closed either with glass stoppers or good corks; if the latter are used, they should be covered with paraffin paper or soaked in melted paraffin wax before being inserted. The bottles are then finally sealed in the usual manner. The scale should be tightly packed into the bottles, which should be completely filled.

3. Determination of Oil in Scale.

(a.) *Press to be used.*—While no one special form of press is recommended for general adoption, the press used must have some arrangement for indicating the pressure applied. The cup, in which the scale is placed during the application of pressure to have an area of 20 square inches.

(b.) *Preparation of the Sample.*—A quantity of the scale, after having been freed from water and dirt, by melting and subsidence, is to be allowed to cool over night to a temperature of 60° F. The solid mass is then ground to a fine powder, a portion of which is used in the determination of the oil.

(c.) *Quantity of Scale to be used.*—The quantity of scale to be used in the determination of oil is to be 250 grains, which quantity may, however, be reduced to 150 grains in the event of the scale containing much oil (over 7 per cent.). With "soft" scale the smaller quantity should be taken.

(d.) *Temperature at which the Scale is to be pressed.*—The temperature of the scale and the press is to be 60° F.

(e.) *Time which the Scale is to remain under pressure.*—The scale is to remain under pressure for 15 minutes.

(f.) *Pressing Cloths and Papers.*—Fine linen pressing cloths and a number of layers of filter paper, sufficient to absorb all the oil, to be used. The exterior papers must not be soiled by oil.

(g.) *Pressure to be applied.*—The maximum pressure is to be 10 cwt. per square inch, and the working pressure 9 cwt. per square inch.

4. Determination of Water in Scale.

The amount of water present in scale may be determined by either of the following processes:—

(a.) *Distillation from a Copper Flask.*—From 1 to 2 lb. of the scale are heated in a conical copper flask of about the dimensions shown in the annexed sketch; this is connected to an ordinary Liebig condenser. By means of a powerful Bunsen burner or lamp, the water, accompanied by a small quantity of light oil, is volatilised and condensed. The distillate is received in a narrow graduated measure, so that the volume of water can be readily ascertained. As a little water usually adheres to the sides of the condenser tube, this is to be washed out with hydrated gasoline or naphtha and added to the principal quantity.

(b.) *Price's Company's Method.*—500 grains of the scale to be tested are weighed in a tared porcelain basin and heated with constant stirring to 230° F., until bubbles cease to be given off: the loss is then determined.

500 grains of the same scale, which has been freed of its water and dirt by melting at a gentle heat and subsidence, are to be heated in the same way, to a similar temperature for the same time, and the loss again determined. The loss

in the second instance is now to be deducted from the loss found in the first experiment, and the remainder is then to be taken as the quantity of water present.

5. Determination of Dirt in Scale.

The amount of dirt present in scale is to be determined by melting a weighed quantity of the scale, and after subsidence, pouring off the clear paraffin. The residue is then mixed with naphtha, thrown on a weighed dry filter paper, washed with naphtha or gasoline, dried and weighed. When available, the quantity of scale to be used in the determination of the percentage of dirt should not be less than 7,000 grains.

6. Calculation of the Results of the Analysis of Scale.

As the oil is determined on scale which has been freed from water and dirt, the result must be calculated back to the original scale containing water and dirt.

7. Determination of the Melting (Setting) Point of Solid Paraffin.

This is to be determined by what is known as the "English" test, i.e., a test tube, about 1 in. in diameter, is filled to the depth of about 2 in. with the melted paraffin, a small thermometer is inserted, and the whole steadily stirred, while the test-tube and its contents are allowed to cool slowly. The temperature at which the thermometer remains stationary for a short time is the melting (setting) point.

II.—FLASHING-POINT OF HEAVY MINERAL OIL.

8. Determination of the Flashing-Point of Heavy Mineral Oil.

The oil cup and cover of the ordinary "Abel" flash-point apparatus is to be employed. The cup is filled with oil in the usual manner, and the rate of heating is to be such that at least 15 minutes are taken in raising the temperature of the oil to 300° F. In the event, however, of a dispute arising as to the correct flashing point of a heavy mineral oil, the question is to be decided by means of the "Pensky-Marten's" apparatus (this Journal, 8, 734).

III.—VISCOSITY OF MINERAL OIL.

9. Determination of the Viscosity of Mineral Oil.

The instrument known as the "Redwood" viscometer, is that which is to be employed in the determination of the viscosity of mineral oils. The instrument is to be standardised according to the directions given by Mr. Boyerton Redwood, in this Journal, 5, 127. Ordinary results are to be expressed, as the time in seconds, which 50 cb. cm. of the oil take to flow through the orifice at a temperature of 70° F.

IV.—SETTING POINT OF MINERAL OIL.

10. Determination of the Setting Point of Mineral Oil.

This is determined in the following manner:—Into a test tube, having a diameter of about one inch and a quarter, the oil to be tested is added to the depth of about two inches, the tube is then immersed in a freezing mixture, the oil being slowly stirred with a thermometer till it is cooled down considerably below the temperature at which solid paraffin first appears; the tube is then removed from the freezing mixture, the oil constantly stirred with the thermometer, and the point carefully watched at which the last trace of solid paraffin disappears. This operation is repeated with the same sample of oil, until two experiments give concordant results, the temperature so found being the setting point.

AN APPARATUS FOR DETERMINING THE FLASH-POINTS OF HEAVY MINERAL OILS.

BY J. GRAY, F.I.C.

THE necessity for a speedy and accurate method of determining the flash-points of heavy mineral oils is fully recognised by those who are called upon to make numerous tests, and perhaps no one is more alive to the uncertainty of the methods which are at present employed than the chemists of the Scotch mineral oil works.

Plan, slide open.

Plan, slide closed.

Elevation.

FLASH-POINT APPARATUS.

It is hardly necessary for me to refer to the old method of taking flash-points, known as the "open test," which is well known to give discordant results, even in the hands of the same operator, according to variable and almost uncontrollable conditions under which the test may be carried out. It is still recommended as "sufficiently accurate for many practical purposes." (This Journal, 9, 902.)

The above method, though still employed in some works laboratories is gradually being superseded by the Abel's cup test, in which the oil cup and cover of the well-known petroleum tester are employed. As a ready mentioned by Mr. Thomson, this method has been adopted by the committee of oil works chemists, provided the time in heating to 300 F. be not less than 15 minutes. I have found that the flash-point of an ordinary Scotch 885 oil will vary as much as 6 F. according as the time of heating varies between 15 and 90 minutes, when the test is carried out with the ordinary Abel's cup. It would therefore be necessary to state the maximum as well as the minimum time of heating, in order to make the results indisputable. With oils having such a wide range of flash-points as those we are dealing with, the fixing of an absolute time is a practical impossibility.

The foregoing method being still unsatisfactory, I was led to design the apparatus I now bring before the Society, with the view of rendering the determination of those flash-points more rapid and accurate. It is an adaptation of the Pensky-Marten slide and stirrer to the Abel cup. Those who now employ the method recommended by the Oil Association chemists, can easily have a stirring arrangement, such as I now show you, fitted to the cup. In working with the Pensky-Marten apparatus, I found the results under varied conditions to be excellent, and was struck with the idea that it could be simplified, and made more suitable for everyday work in the technical laboratory.

The stirrers, consisting of two sets of vanes, one in the oil and the other in the vapour space, are attached to a vertical shaft passing through the cover and terminating at the top in a small bevelled wheel, the bevel of which is milled. A horizontal shaft (carried on two supports) terminates at one end with a bevelled wheel gearing with the one on the stirrer shaft, and at the other end with a disc carrying a small handle with which to rotate the shaft. This shaft also carries a collar with two pins projecting about $\frac{1}{4}$ in. at diametrically opposite points. By sliding the shaft slightly to the right, the bevel wheels are put out of gear, and the pins projecting from the collar are drawn into position for actuating the testing arrangement. This consists of a sliding cover on the top of the lid proper, so arranged that when the former is moved it depresses the pip light to the proper point, and brings the orifices opposite those on the fixed lid. There are three orifices, one, at which the test light is applied, the other two, situated one at either side of it, being for the admission of air. It will thus be readily seen that the change from stirring to testing and *vice versa* can be instantly performed.

The results got by this apparatus are identical with those got by the Pensky-Marten. They are not affected by the source of heat, a naked flame giving the same results as the sand-bath. It is immaterial what the rate of heating is, provided it is not too rapid to prevent a correct reading of the thermometer. I prefer to reduce the rate of heating when nearing the point at which the oil is expected to flash. The stirrers do not require to be worked continuously but merely at intervals. I find it advisable to stir more frequently when the rate of heating is fast.

The apparatus is made by, and may be had from Messrs. Baird and Tatlock, Glasgow.

Obituary.

FRANCIS CLARK BLAKE.

SOMETIME ADJUNCT-PROFESSOR OF CHEMISTRY IN LAFAYETTE COLLEGE AND SUPERINTENDENT WITH THE PENNSYLVANIAN LEAD COMPANY; MEMBER OF THE SOCIETY OF CHEMICAL INDUSTRY.

THE subject of this obituary was born in Cumberland, Maine, February 23rd, 1854, and died in Helena, Montana, February 21st, 1891. He was the son of the Rev. Joseph Blake, late of Andover, Mass. A few years after his birth his family moved to Wells, Maine, where his youth was passed, and his remains now lie.

F. C. Blake, being the minister's eldest son, was obliged to push out into the world at an early age to make a way for himself. He was a hard worker from the beginning, and owed all his successes to his own unaided efforts. The extensive works of Washburn and Moen, of Worcester, Mass., formed the first scene of his labours, and here he learned the trade of machinist. Thereafter he entered the Worcester Polytechnic Institute, and, working his way through the school, graduated in the course of Physics in 1876.

In 1877 he was called to Lafayette College to take the position of Adjunct-Professor of Chemistry, which he filled with honour and ability for two years.

At Easton he later on became acquainted with the daughter of Dr. Ballard, Professor of Moral Philosophy, who became his wife in 1885. In 1879 he accepted the position of Assistant Superintendent with the Pennsylvania Lead Company, whom he served most faithfully daily until the time of his death. On the resignation of the Superintendent, Mr. E. F. Enrich, in 1881, Mr. Blake was appointed to succeed him. For 10 years he devoted all his energies and talents to the development and improvement of the great refinery entrusted to his care. The works as they stand to-day are a substantial monument to his genius and fertility of resource.

Mr. Blake was a great lover of books, and accumulated in a few years of his business life one of the choicest and most extensive scientific libraries west of the Alleghanies.

In the notice of his life and death contained in the *Eng. and Mining J.*, 1891, 323, from which the foregoing information has been mainly culled, his personal character is thus summed up:—"He was a quiet, strong, earnest, genuine man. But perhaps the most striking characteristic of all was his kindness of heart, and his readiness, nay, eagerness, to help others to bear their burdens."—W. S.

Journal and Patent Literature.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

PATENTS.

A Composition suitable for Lining Casks and like Vessels, and for Making Screw Stoppers for Bottles. W. Sinclair, Hull, and M. Mackay, London. Eng. Pat. 1177, January 22, 1890. 4d.

See under XIII., page 375.

Improvements in Lining Boilers or Digesters used in the Manufacture of Paper-Pulp and for similar Purposes. C. Kellner, Vienna, Austria. Eng. Pat. 6951, May 6, 1890. 4d.

See under XIX., page 381.

II.—FUEL, GAS, AND LIGHT.

Steam Boiler Experiments. Nos. 1, 2, 3, 4 and 5. Bryan Donkin, jun., and Professor Kennedy. Engineering, 1890, 50, 1—2, 59—60, 120—122, 591—593; 1891, 51, 236—238.

THE authors point out that in all boiler trials hitherto made, different kinds of coal have been used for the different boilers, so that useful economical comparisons of the experiments are difficult. They therefore have undertaken a series of very elaborate experiments on some of the chief types of boilers in general use, employing the same kind of coal in each case. To do this about 100 tons of a good Welsh coal—Nixon's steam navigation—was procured and thoroughly mixed to insure uniformity. The boilers tested included the following types:—

Fires Internal.

(1.) Lancashire boiler with two fires and two tubes. With and without forced draught.

(2.) Railway locomotive or tubular boiler, both fixed and running on rails. With exhaust steam going into chimney.

(3.) Cornish boiler, one fire and one flue. With ordinary chimney draught.

(4.) Cornish multitubular boiler. With ordinary chimney draught.

(5.) Small vertical fire-engine type. With exhaust steam into chimney.

(6.) Vertical tubular. Ordinary chimney draught.

(7.) Tubular locomotive, or agricultural type. With ordinary chimney draught.

Fires External.

(8.) Elephant, or French type } With ordinary

(9.) Water tube, or Root type } chimney draught.

One fire.

* Any of these specifications may be obtained by post, by remitting the cost price, plus postage, to Mr. H. Reader Luck, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. The amount of postage may be calculated as follows:—

If the price does not exceed 8d.	1½d.
Above 8d., and not exceeding 1s. 6d.	1d.
" 1s. 6d., " " 2s. 4d.	1½d.
" 2s. 4d., " " 3s. 4d.	2d.

For all the trials a uniform programme was laid down, details of which are fully given in the paper, showing that every possible point was considered, and that the greatest care was taken to ensure exactness in the various measurements. The paper is divided into the following parts:—

I. Description of the standard coal used, its analysis and calorimetric value, amount of ash, moisture, clinker, pure and dry coal, amount of air theoretically required, &c.

II. Methods adopted and instructions followed in the various trials, with particulars and analysis of gases, method of calculating heat balance, graphic representation of results, and tests for radiation.

III. Remarks and notes relating to each experiment.

IV. Tables of results of the standard boiler tests, and the additional tests with other coal.

V. Steam engine trials executed at the same time as the boiler tests.

VI. Comparison of the results, &c.

In Part I. are given complete analyses and calorimetric determinations of the coal, as well as the calculated heat value of 1 lb. independent of the water and the incombustible

matter it contained. This last result, which is called "per lb. pure and dry," is 15,560 thermal units (Fahrenheit). From this is calculated the theoretical evaporative value of 1 lb. of the pure and dry coal, which is 16.1 lb. of water from and at 212° F.

In Part II. are given the results of the practical experiments with the various boilers tried. These results, which have appeared from time to time in "Engineering," are not yet exhausted, and up to the present only those of the first seven experiments have been published. These show that most minute precautions were taken to catch and try to account for every thermal unit of the fuel used. Full descriptions, drawings and dimensions of the boilers are given, as well as every detail in connexion with the work. Every factor has been taken into consideration, and the results are given in elaborate tables, as well as being plotted out in the form of curves. A *balance sheet* of the heat evolved and absorbed has been worked out, and is given with each experiment. As the amount of heat evolved is taken as the same in each case (100 per cent., from pure and dry coal), the results of the heat absorbed may be compared in the following table:—

HEAT ABSORBED PER CEN.

Experiment.	1.	2.	3.	4.	5.	6.	7.
Heating and evaporating water... Boiler.....	67.8	79.4	67.6	66.2	56.8	62.5	60.1
Economiser....	11.9	11.7
Heating furnace gases.....	9.4	13.6	16.2	22.5	31.8	13.8	15.3
Evaporating moisture in coal.....	0.1	0.1	0.1	0.1	0.0	0.1	0.1
Radiation.....	1.5	7.0	6.0	5.2	9.1	6.5	6.3
Heat in fire drawn.....	0.1	0.3	0.1	0.2	0.1
Evaporating water under grate.....	..	3.1	1.6
Lost by imperfect combustion.....	12.7	0.0	1.2	0.0	0.0	2.1	0.8
Unaccounted for.....	0.4	1.9	3.6	5.8	1.6	2.8	7.7
	100.0	100.0	100.0	100.0	100.0	100.0	100.0

The type of boiler used in each case was as follows:—

Experiment 1. — Vertical, tubular, internal fire, no economiser; at B. Donkin's works, London (mean steam pressure above atmosphere, 35 lb.).

Experiment 2. — Lancashire, with conical tubes in flues, no economiser; at B. Donkin's works, London (mean pressure, 50 lb.).

Experiment 3. — The same as experiment 2 (mean pressure, 57 lb.).

Experiment 4. — Locomotive, no economiser; at the Engineering Laboratory, University College (worked at atmospheric pressure).

Experiment 5. — The same as experiment 4; at the Engineering Laboratory, University College (under pressure of 85 lb. and reduced area of grate).

Experiment 6. — Water tube, De Naeyer's system; near Liège, in Belgium (mean steam pressure, 86 lb.).

Experiment 7. — Same as experiment 6 (steam pressure, 75 lb.).—A. W.

The Valuation of Coal. H. Bunte. J. 4. Gasbeleuchtung, 34, 21–26 and 41–47.

THE earliest method in use for the calorific valuation of fuel consisted in employing Dulong's formula, which added together the heat evolved by the combustion of the carbon, sulphur and hydrogen present, subtracting from the latter the amount necessary to form water with the oxygen, as follows:—

$$C \cdot 8080 + (H - \frac{O}{8}) \cdot 28,800 + 2,000 S = 600 W$$

W standing for the amount of water existing in the coal)

In the year 1867 Scheurer-Kestner and Meunier (Bull. Soc. Ind. Mulhouse, 1868; Compt. Rend. 69, 414; 73, 1061; and 77, 1587) conducted a series of experiments in a calorimeter resembling that of Favre and Silbermann, which tended to show that the results obtained in the former way were from 10 to 17 per cent. too low, and that from the chemical composition of the fuel only approximate ideas as to its commercial value could be obtained. As these experiments were carried out on small samples of coal (0.3–0.5 gm.) it was felt advisable to repeat them on a larger scale, and the Polytechnische Verein of Munich put up a plant capable of burning from 200 to 300 kilos. at a time.

This apparatus, for a detailed description of which reference must be made to the original article, consists of a calorimeter in which the heat absorbed in boiling water is measured by the rise of temperature of a limited quantity of condensing water, and which is so arranged that samples of the escaping gases can be from time to time collected, and the amount of carbonic acid estimated. Experiments conducted by the author and others in this apparatus, and also by the author in calorimeters devised by Berthelot and Fischer, on a large number of different sorts of coal, show a maximum deviation from Dulong's formula of + 3.7 and + 2.8 per cent., and that *so close a connexion exists between the chemical constitution and the heat evolved during the combustion of a coal, that the figures obtained from its ultimate analysis may be confidently employed for calculating its commercial value.* Full particulars of the experiments and analyses on which these conclusions are based, will be found in the paper.

In practice the same coal burnt under different conditions is often found to give widely different results, owing to

the greater or less loss occurring during the process. This loss is dependent on the amount of carbonic acid in the waste gases, being the greater when the carbonic acid is less and the excess of air supplied to the furnace is greater; and the less the higher the percentage of carbonic acid present in the waste gases. Four experiments conducted on coke under precisely similar conditions, excepting as to the amount of air supplied to the furnace, yielded the following results:—

No. of Experiment	In Waste Gases.	
	CO ₂	Total Heat Evolved.
	Per Cent.	Per Cent.
1	8.0	22.0
2	10.8	16.0
3	13.8	13.0
4	14.9	10.0

Other experiments on various sorts of coal gave similar results, showing that at a temperature in the flues of 250° when the amount of carbonic acid was 9 per cent., the loss of heat was 20 per cent., while with only 7 per cent. of carbonic acid the loss rose to about 26 per cent.; but owing to the fact that when air is supplied in large excess the temperature of the gases is usually far higher, the loss occurring must be considerably greater than indicated by these figures.

To trace the connexion between the amount of carbonic acid gas in the waste gases and the economy of combustion, the following considerations are submitted. When 0.536 gram. of pure carbon (the weight necessary to form 1 cbm. of CO₂) is burnt in a closed vessel containing 100 cbm. of air at a temperature of 0°, the heat evolved may be calculated to be sufficient to raise the whole to 141°; on doubling the amount of carbon so that the air after combustion contains 2 per cent. of carbonic acid, the temperature will be 281°. In this way a table may be constructed in which the temperature rises approximately 140° for each additional 1 per cent. of carbonic acid. By denoting this temperature by T and the temperature of the waste gases by t, the available heat per cent. may be represented by the expression $\frac{T-t}{T}$.

Thus, with 5 per cent. of carbonic acid and a temperature of 300° above that of the surrounding air, the loss of heat is 43 per cent., and with 10 per cent. of carbonic acid at the same temperature 22 per cent.

To see how far these theoretical considerations apply in practice four experiments were tried on coke in the above-mentioned apparatus and the loss of heat occurring directly estimated:—

	1.	2.	3.	4.
CO ₂ in waste gases, per cent.	8.0	10.2	13.8	14.9
Temperature of waste gas (t)	218°	203°	192°	174°
Loss of heat found	21%	15%	12%	10%
Loss of heat calculated, $\left(\frac{T-t}{T}\right)$	20%	14%	10%	8%

In the case of coal, experiments point to the fact that within certain limits a difference between the theoretical and practical loss of not more than 2—4 per cent. may be expected, with respect to which the author proposes shortly to give further details.—F. H. L.

On the Heat of Combustion of the Commoner Illuminants, and the Contamination of the Air caused by their Use.
E. Cramer. J. f. Gasbeleuchtung, 34, 27—31, 48—50 and 65—68.

THE substances examined by the author consisted of candles (made of tallow, paraffin* and stearin), paraffin oil and gas. The tallow candles were moulded, as being more uniform in composition. The paraffin candles were the German standard candles, and the gas was that supplied to the town of Marburg, which, however, differing as it does only slightly from that made in other places, may be said to be of average composition. Both the petroleum and gas were burnt so as to produce a light of about one-candle power. In the following table the "total heat" represents the total amount indicated by the calorimeter, and the "actual heat" the amount rendered latent by the evaporation of the water formed during the combustion subtracted from the total. The weight of substance burnt was in each case one gramme.

TABLE I.

Substance.	Total Heat.	Latent Heat.	Actual Heat.	Per Cent. of Heat.	
				Latent.	Actual.
Gas.....	12,483	1,150	11,332	9.22	90.78
Petroleum...	11,063	679	10,384	6.07	93.93
Paraffin.....	10,618	728	9,890	6.86	93.14
Stearin.....	9,178	626	8,552	6.82	93.18
Tallow.....	8,720	600	8,111	6.98	93.01

The amount of water formed by the combustion of 1 gram., and also the relative amounts of water and of "actual heat," representing tallow as 100, are shown in Table II.

TABLE II.

Substance.	Water Formed.	Relative Amounts of	
		Water.	"Actual Heat."
Tallow.....	0.973	100	100
Stearin.....	1.017	104	104
Petroleum (3 hours)	1.088	112	128
Paraffin.....	1.220	125	122
Petroleum (8 hours)	1.271	131	128
Gas.....	1.867	192	140

The differences in the case of the petroleum lamp when kept burning for three or eight hours are due to the fact that for the first hour or two the combustion is not so perfect as later, carbon being deposited on the wick. On burning the substances so as to obtain a light of 100 candles, the results per hour are given in Table III.

To estimate the amount of carbon incompletely burnt, the original substances were analysed, and from the amount of carbon so found was subtracted that passing away in the waste gases in the form of carbonic acid; this method appearing preferable to the one formerly employed, which consisted in passing a sample of the gases over red-hot copper, and calculating the increase of CO₂. The figures given in Table IV, show the results of burning one gramme of the various substances.

* Throughout this abstract the word "paraffin" signifies the solid used for the manufacture of candles, and "petroleum" the "burning oil."

TABLE III.

Substance.	Amount Burnt.	CO ₂ Produced.	Water Vapour.	Heat Units.
Gas: Siemens' regenerative lamp.	Cbm. 0.35	Kilos. 0.386	Kilos. 0.304	1843
Gas: Argand.	0.80	0.882	0.604	4213
Petroleum: Flat burner (3 hours).	0.50	1.648	0.653	5620
Petroleum: Flat burner (8 hours).		1.876	0.762	
Petroleum: Large round burner (3 hours).	0.20	0.549	0.218	2073
Petroleum: Large round burner (8 hours).		0.625	0.254	
Paraffin.	0.77	2.298	0.911	7615
Stearin.	0.92	2.443	0.956	7881
Tallow.	1.00	2.681	0.991	8111

TABLE IV.

	Weight of Carbon.		Relative Amounts.	
	By Analysis.	In Waste Gases as CO ₂	Incompletely Burnt.	As CO ₂ Incompletely Burnt.
Gas	0.643	0.647	0.016	99
Tallow	0.740	0.730	0.010	113
Stearin	0.763	0.726	0.037	112
Paraffin	0.830	0.821	0.018	127
Petroleum (3 hours)	0.858	0.754	0.107	116
Petroleum (8 to 10 hours).	0.878	0.853	0.005	132

For a light of 100 candles, these figures become—

	Cbm. CO ₂
Siemens' burner	0.39
Argand burner	0.88
Petroleum small and flat flame	1.65
Petroleum large and round flame	0.55
Candles	2.3—2.7

Table V. gives the amount of hydrogen incompletely burnt, the results being obtained by feeding the flame with dry air, and estimating the amount of water in the gases.

TABLE V.

	Weight of Hydrogen.		Relative Amount Incompletely Burnt.	
	By Analysis.	In Waste Gases as H ₂ O	Incompletely Burnt.	As H ₂ O
Tallow	0.118	0.108	0.010	100
Stearin	0.124	0.113	0.011	110
Paraffin	0.132	0.115	0.017	170
Petroleum (3 hours)	0.138	0.121	0.017	170
Petroleum (8 hours)	0.138	0.111	0.009	100
Gas	0.256	0.207	0.049	100

With regard to the loss of heat occurring during the combustion of the various illuminants, Table VI. shows the difference between the total heat registered by the calorimeter

and the theoretical amount given off by one gramme. The figures in the case of stearin and tallow are the result of direct analysis, the others being calculated from the probable composition of the substances, the gas being considered to be dry.

TABLE VI.

	Total Heat.		Loss.
	Theoretical.	Observed.	
Gas (1 litre)	6.974	5.949	2.6
Stearin	9.745	9.178	6.0
Tallow	9.423	8.720	7.5
Petroleum	12.000	11.036	8.0
Paraffin	12.000	10.618	11.5

The products of the incomplete combustion of the hydrogen and carbon include carbonic oxide, nitrous and nitric, sulphurous and sulphuric acids; the author has only been able to investigate the amount of nitrous acid formed during the burning of stearin candles: his results are 0.126—0.322 mgrms. of HNO₃ per gramme of stearin. The experiments will shortly be continued.

Experiments with guinea pigs prove that healthy animals are able to breathe air contaminated with the products of combustion of stearin candles or a gas burner for days at a time without permanent injury to their health; but in case of human beings, the nose so quickly detects small quantities of "carbonic acid" and nitrous fumes that no one is able to inspire air containing these substances in quantities far below their injurious limits without great inconvenience.—F. H. L.

The Freezing of Gas Mains. J. f. Gasbeleuchtung, 34, 81.

THE recent severe weather has attracted special attention to the inconvenience caused through the freezing of the water in gas mains, and to the question of the possibility of its avoidance during subsequent winters by the drying of the gas before leaving the works. Seeing, however, that special purifiers of large size would have to be put down, and that to keep the mains dry they would have to be at work all through the year, this plan becomes impracticable, and the only alternative is to lay the mains so deep that they always remain above the freezing point (this Journal, 1889, 949).

—F. H. L.

The Measurement of Natural Gas with the Pitot Tube Gauge. S. W. Robinson. Engineering and Mining J. 1891, 261—262.

THE Pitot tube-gauge is a simple and accurate instrument for measuring the velocity of a current of fluid. This velocity, multiplied by the sectional area of the stream, gives the volume of fluid which passes any cross section of the tube in unit time. An idea of the principle on which the action of the instrument depends may be obtained from Fig. 1, which represents a manometer used for the purpose of measuring the pressure under which natural gas escapes from the mouth of an oil well. Here the external static pressure is that due to the atmosphere acting on the limb F. The limb B is bent down so as to face the issuing gas. The difference in pressure is measured by a column D, E, F of water or mercury: when greater pressures have to be measured, a pressure gauge is used instead, as in Fig. 2. Tables have been prepared giving the velocities corresponding to various differences of pressure.

Fig. 3 shows the actual form of gauge used for measuring the flow of natural gas in pipes. It has been used in pipes where the pressure was above 100 lb. per square inch without inconvenience or detraction from accuracy of results. The tip A, B is seen to have two openings: A is the Pitot tube mouth proper; B is a lateral opening in the smooth uniform side of the tip. B may be at some distance

from A; but it is most convenient to make the double tip so that it can be screwed air-tight into a $\frac{1}{8}$ -inch hole. The end AB is bent at an angle of 90°, so that A faces the current while B is so placed that the velocity of the gas has no effect, the static pressure alone being transmitted. Thus the pressure exerted at A when the instrument is in use on a pipe line, is equal to the static pressure in the pipe, plus the pressure due to impact, or to the velocity of the current. The figure shows that the pressure at A is transmitted to C, and that at B to D. The difference in pressure is measured by the manometer C D, which consists of a glass tube containing water or mercury. When used for measuring flow from the mouth of gas wells the instrument would be placed just at the mouth, and the pressure transmitted through the side opening would be simply that of the atmosphere; hence the simple manometer shown in Figs. 1 or 2 is all that is required in this case. The complete gauge shown in Fig. 3 is especially designed for measuring the flow of gas in pipe lines. It should be placed so as to receive the normal flow of gas, away from pipe connexions, tees, &c., which cause eddies. The tip should be held at one-fourth of the diameter, or, if at the centre, the apparent volume should be multiplied by 0.97 to correct the so-called velocity curve. The volume (in cubic feet) of gas flowing per hour through the pipe may be found from tables or calculated from the expression—

$$V \text{ per hour} = 1690 d^2 \sqrt{h \left(1 + \frac{p}{15}\right)}$$

where p is the gauge pressure in pounds per square inch, d the inside diameter of the pipe in inches, and h inches of water, the temperature of the flowing gas being taken at 40° F. and that of storage at 50°.

Fig. 1.

Fig. 2.

Fig. 3.

Results are given of a series of 21 tests made with a "gas-meter prover," where a known volume of air was forced

through a pipe in a measured interval of time; these show that the errors amounted to less than 3 per cent. Tests made with a Westinghouse natural-gas meter gave similar results.—D. E. J.

PATENTS.

Improvements in the Means Employed in Burning Gas or Oil for Lighting or Heating Purposes. W. Potts, Edinburgh. Eng. Pat. 115, January 3, 1890. 8d.

IN order to effect a slower burning and a more complete combustion of the gas or oil, the products of combustion are discharged along a lateral, instead of a vertical, line of flow; this is effected by having the burner-glass spherical below but funnel-shaped above, and supporting a metal or other reflector on the burner-glass by wires, in such a way that a space of about three-eighths of an inch is left through which the products of combustion may escape; in this way discolouration of ceilings is avoided. The gas is heated by passing through a coil of tube, forming the burner socket, instead of the usual straight passage, and three or more flat flame nibs may be fixed in the socket. An improved form of gas street-lamp and a corrugated form for oil lamp-wicks, to enlarge the burning surface, are also described.

—F. S. K.

Improvements in and Connected with Furnaces for Burning Liquid Fuel. C. A. Sahlström, London, and A. F. Hill, West Brighton. Eng. Pat. 2670, February 8, 1890. 8d.

INSTEAD of setting the upper portion of the fire-chamber of a cupola vertically or nearly so above the widened lower portion, the patentees construct it at an angle of 60° or 45°, but varying according to the nature of the material to be melted.

The essential features of the furnace described are:—(1.) The enlarged fire-chamber with a dome-shaped roof combined with an air space and provided with adjustable hydrocarbon burners, and, if necessary, with a fixed or moveable receiver for the molten metal. (2.) The inclined upper portion of the chamber, which is contracted below and provided above with a charging door. (3.) The vertical flue containing super-heated steam pipes, which are utilised for the supply of steam to the hydrocarbon burners.

—F. S. K.

Improvements in Apparatus for Utilising Liquid Hydrocarbons for Lighting and Heating. R. H. Doty, London. Eng. Pat. 3242, February 28, 1890. 8d.

THIS patent relates to an improvement on the burner of the apparatus previously described in Eng. Pat. 8697 of 1887.

The burner is constructed with an upper and a lower annular chamber connected with each other by vertical tubes of wrought iron, or other material in which the hydrocarbon is volatilised. The vapour passes through the upper chamber to a burner arranged within the space enclosed by the chambers and tubes; the annular chambers are so constructed that portions of them may be easily removed so as to permit of the vertical tubes being cleaned.

There are two claims and one sheet of drawings.

—F. S. K.

Improvements in Separating Hydrogen Gas and the Light Carburets of Hydrogen, such as Methane, from Water-Gas or Producer-Gas, or from both of them when mixed together. B. C. Sykes and G. Blamires, Cleckheaton. Eng. Pat. 3332, March 3, 1890. 6d.

THE water- or producer-gas from a gasometer is passed under some pressure through porous tubes suitably arranged in a larger metal tube; the lighter gases, such as hydrogen and methane, which diffuse through the porous tubes more quickly than the heavier gases, are drawn off from the outer and larger tube by an exhaustor and passed into a gasometer, whilst the heavier gases pass on and are stored separately. When the lighter gases are required for domestic heating they can be further purified, if necessary, by repeating the process; in this way every vestige of carbonic oxide and nitrogen can be removed.—F. S. K.

Improvements in Incandescent Gas Lamps. A. Wenzel, Czernowitz, Austria. Eng. Pat. 3767, March 10, 1890. 6d.

THE incandescent gas lamp described in this patent is well adapted for use in an inverted position; it consists of a burner formed of two concentric nozzles, and a disc, rod, or grating of magnesia, placed on a suitable support attached to the burner, the whole being enclosed in a suitable perforated glass cover. Illuminating gas is passed through one of the burner tubes, the other being supplied with oxygen, hydrogen, water gas, oxyhydrogen gas or air, either singly or mixed together.

The magnesia disc is prepared by heating magnesium nitrate until the oxides of nitrogen have been driven off, pouring the molten mass on to a plate (covered with paper), and then hardening the cake by heating it again to complete the decomposition.

There are three claims and one sheet of drawings.

—F. S. K.

Improvements in the Manufacture of Artificial Fuel. H. H. Lake, Middlesex. From J. Lundström & Co., Stockholm. Eng. Pat. 11,115, September 8, 1890. 4d.

TWO blocks of fuel are prepared by mixing the small coal produced in breaking anthracite with an adhesive paste made of finer coal, coal-dust, peat, sawdust, &c., and a solution of silicate of soda; the mixture is then moistened with a solution of common salt containing 5 to 50 per cent. of calcium chloride in order to hasten solidification, pressed or moulded into suitable forms, and dried if necessary.

—F. S. K.

Improvements in Gas Furnaces for use in Glass and other Works. R. J. M. Regnault, St. Denis, France. Eng. Pat. 20,606, December 17, 1890. 6d.

GAS furnaces employed in glass works have hitherto been provided with two distinct gas-producers and two distinct grates, in order that the supply of gas may be kept up while one or the other is being cleaned out. The patentee describes an arrangement of furnace with a single inclined grate of such dimensions that two (or more) feeding holes can be placed above it, and so constructed that one half of the grate can be charged without in any way interfering with the proper working of the other. This arrangement diminishes the cost of construction and is more economical as regards fuel. —F. S. K.

Phenol of Birchwood Tar. M. Pfrenger. Arch. Pharm. **228**, 713—719.

THE raw material used, a brownish-yellow refractive liquid of acid reaction and sp. gr. 0.956 at 15°, was the *Oleum betulini ætherium rect.* By first washing with sodium carbonate solution and then with water, all acid was removed, subsequent repeated treatment with aqueous potash yielding the *phenoxide*. The phenol was separated

from the latter by means of sulphuric acid. It was then taken up with ether, well washed, and then dried with sodium sulphate. The purified phenol was fractionated. At length a fraction boiling between 181° and 191° was obtained, and probably consisted of *creosol* with a little *phenol*.

When heated with zinc-dust, the fraction boiling between 191° and 200° yielded chiefly *toluene* and a little *anisole*. When heated at 150° C. with methyl iodide and some methyl alcohol, the same fraction yielded *methyl cresyl ether* and a small quantity of *catechol dimethyl ether*. The fraction boiling between 200° and 205° was dissolved in ether and heated to 80° with alcoholic potash; on cooling, dissolving the crystalline product in water, decomposing with hydrochloric acid, and purifying the separated product, *guaiacol* was obtained.

Heated at 150° with methyl iodide, the same fraction yielded mainly *catechol dimethyl ether* and a little *methyl cresyl ether*.

When melted with potash, the fraction distilling between 206° and 211° yielded *hydroxy-isophthalic acid*.

The fraction 218° to 221° behaved with reagents like *creosol*.

Thus the constituents of this birchwood tar creosote are traces of phenol, *creosol*, *guaiacol*, 1, 3, 4-xyleneol, and 1, 3, 4-*creosol*. The bulk of the creosote consisted of *guaiacol* and 1, 3, 4-*creosol*.

On the Imperfect Solubility of Mineral Oils in Petroleum Spirit. Bender. Mitt. Königl. tech. Versuchs. 1890, 311—316.

DARK mineral oils, dissolved in benzene, are apt after some time to deposit fine precipitates. The filtration of these precipitates is difficult; good results, however, are obtained by using filter-paper containing asbestos. After having washed the precipitates and dried them at 100—110° C., it was found, by weighing, that the quantities of the insoluble substances contained in three different mineral oils were 1.8, 2.0, and 1.8 per cent. respectively. The precipitates consisted of a fine powder, resembling dark brown coal, having a slight bituminous smell and a higher specific gravity than water. The melting point is above 110° C., and the powder, if ignited, burns with a smoky flame. It is insoluble in the various kinds of petroleum spirit, slightly soluble in ether, but easily so in heated petroleum. It dissolves easily in carbon bisulphide, benzene, ether, chloroform, and in a mixture of ether and chloroform. These results indicate that the precipitates thus obtained belong to those organic substances which are formed by the oxidation of petroleum, the most important of which is asphaltum. H. S.

PATENT.

An Improved Process for Rendering Tar Oils Soluble in Water and the Production of Disinfectants and other Useful Products therefrom. W. Dammann, Halle, Germany. Eng. Pat. 1017, January 20, 1890. 6d.

See under XVIII. C., page 380.

IV.—COLOURING MATTERS AND DYES.

A New Synthesis effected by Diazo-Compounds. R. Hirsch. Ber. **23**, 3705—3710.

TEN grms. of aniline were dissolved in 30 grms. of hydrochloric acid (30 per cent.) and 200 cc. of water, and diazotised by adding a solution of 7.5 grms. of sodium nitrite in 50 cc. of water. The solution was heated to 50° for two hours when the diazo-compound was completely decomposed. The end of the reaction was determined by adding an alkaline solution of β naphthol sulphonic acid,

when no colouration was produced. The solution, after distilling until only traces of phenol remained, was allowed to stand. After 15 hours a few crystals separated. The experiment was repeated with large quantities of material, and the crystalline body was found to be hydroxydiphenyl. The compound is identical with that of Latschinoff obtained by the action of potash on diphenylmonosulphonic acid. The same compound is obtained by diazotising para-amido-diphenyl. The formation of this compound appears to be due to the action of phenol on diazobenzene as follows:— $C_6H_5OH + C_6H_5N \cdot N \cdot O \cdot C_6H_5 = C_{12}H_{10}O + N_2 + HCl$. To determine this point the following experiment was made. A solution of 50 grms. of aniline in 500 cc. of water was diazotised and shaken repeatedly with a mixture of 100 grms. of phenol with 10 per cent. of water. The product, which contained a considerable quantity of diazobenzene in solution, decomposed energetically, on warming, with evolution of gas. Other solvents, such as benzene, chloroform, ether, anisol, &c., do not extract diazobenzene from an aqueous solution. Since phenol dissolves diazobenzene with an intense orange colour, the author ascribes it to the formation of diazo-oxybenzene, $C_6H_5N : N \cdot O \cdot C_6H_5$. The cresols act similarly.

After decomposing the solution of phenol and diazobenzene on the water-bath, it was distilled in fractions. About $\frac{4}{5}$ per cent. boiled at 230—290°, and contained 8 per cent. of phenol and 1 per cent. at 290—325°, which solidified on cooling. After a second fractionation the product boiling above 200° was dissolved in toluene and shaken up repeatedly with caustic soda solution. The alkaline solution became deep blue and oxygen was evidently absorbed. The toluene separated from the caustic soda and fractionated yielded diphenyl ether and a neutral oil, which was probably $C_{12}H_{10} \cdot O \cdot C_{12}H_{10}$. The alkaline solution, acidified and shaken up with toluene, yielded a mixture of the two isomers *p*- and *o*-hydroxydiphenyl. The blue colouring matter was not isolated, but was probably similar to the compound obtained by the action of phenol upon nitrosophenol, the leuco-compound of which is *p*-dihydroxydiphenylamine.

The homologues of aniline, benzidine, and naphthylamine react similarly with phenol and with *o*-, *m*-, and *p*-cresol.—J. B. C.

Formation of Quinalizarin from Alizarin. C. Graebe. Ber. 23, 3739—3740.

It has been shown by René Bohn that bluish-green colouring matters are obtained by warming sulphuric acid with alizarin blue (Germ. Pat. 46,654). The author has found, in conjunction with Muhlert, that these are derivatives, not of dihydroxy- but of tri- and tetrahydroxyanthraquinone, and that by splitting off the sulpho-groups, a product is obtained consisting chiefly of tetrahydroxyanthraquinone.

Bohn has extended the reaction to alizarin, the purpurin, anthragallol, &c., and it is found that the product obtained by heating the first named with 100 per cent. sulphuric acid consists of a mixture of tri- and tetrahydroxyanthraquinone. The latter is identical with Liebermann's quinalizarin, and is therefore a 1,1',2,1' tetrahydroxy compound. Neither this substance nor the trihydroxy-derivative yield phthalic acid on oxidation.—H. G. C.

Phenazines. K. Eicker. Ber. 23, 3803—3810.

O. FISCHER and Hepp (this Journal, 1890, 603 and 1028) have described the synthesis of amidonaphthaphenazine, and the author has applied their method to the preparation of other phenazines.

Benzene-azo-a-ethyl-naphthylamine separates from a mixture of ether and petroleum spirit in red prismatic crystals, with a bluish reflection, melting at 88°.

Benzene-azo-a-dimethylnaphthylamine is prepared by the action of diazobenzene chloride on *a*-dimethylnaphthylamine; its hydrochloride forms deep indigo-blue needles, melting at 105°.

a-Ethyl-amido-a-naphthaphenazine—

is formed when 1 : 2 phenylenediamine (1 mol.) is heated with benzene-azo-ethyl-naphthylamine hydrochloride (1 mol.) and alcohol (2 parts), in a sealed tube, for 5—6 hours at 140°. The *hydrochloride* is obtained from the solid portion of the melt after washing it with dilute alcohol, and from the liquid portion by precipitation with water; it is purified by repeated crystallisation from alcohol. The *base* separates from its solution in benzene, on addition of petroleum spirit, as a yellow crystalline powder, which sublimes in woolly needles, undergoing meanwhile partial carbonisation. It is insoluble in water and in alkalis, and sparingly soluble in chloroform, ether, benzene, and cold alcohol; its solutions show a yellow-green fluorescence. The *hydrochloride* forms garnet red and the *nitrate* reddish-brown glistening needles.

The *platinohchloride* ($C_{17}H_{13}N_3HCl_2$), $PrCl_6$, is a scarlet-red precipitate, consisting of microscopic needles, insoluble in water and sparingly soluble in alcohol, and the *azochloride*, $C_{17}H_{13}N_3HCl$, $AlCl_3$, a red micro-crystalline powder, sparingly soluble in alcohol. The *acetyl-derivative*, $C_{20}H_{17}N_3O$, forms small straw yellow rhombic crystals from glacial acetic acid. On heating the *base* with concentrated hydrochloric acid at 175°—180°, the group, $NH \cdot C_2H_5$, is replaced by hydroxyl, ammonia and alcohol being formed (compare O. Fischer and Hepp, loc. cit.).

a-Ethyl-amido-a-naphthatolazine—

is prepared from benzene-azo-a-ethylnaphthylamine and tolylenediamine [$CH_3 : NH_2 : NH_2 = 1 : 3 : 1$], under the same conditions as the foregoing compound, which it closely resembles, but is less soluble in the solvents mentioned; it forms yellow stellate groups of needles or plates, melting at 182°. The *hydrochloride* and the *sulphate* crystallise in copper-glistening needles, and the *nitrate* in brown-red needles, having a bronze shimmer. The *platinohchloride*, *aurochloride*, and *acetyl-derivative* resemble the corresponding compounds of the foregoing base.

a-phenyl-amido-a-naphthatolazine, $C_{23}H_{17}N_3O$, prepared from tolylenediamine [$CH_3 : NH_2 : NH_2 = 1 : 3 : 4$], and benzene-azo-a-phenylnaphthylamine hydrochloride (compare Fischer and Hepp, *Annalen* 256, 256) crystallises from alcohol in yellow needles, melting at 214°; it is sparingly soluble in most solvents, and does not sublime readily. The salts are sparingly soluble; the hydrochloride forms small brown-red, and the nitrate brown glistening needles from alcohol. The platinohchloride crystallises in dark red microscopic needles, sparingly soluble in alcohol, insoluble in water, and the aurochloride is a brown-red crystalline powder.

a-Dimethyl-amido-a-naphthaphenazine—

is obtained from 1 : 2 phenylenediamine and benzene-*a*-dimethylnaphthylamine. The melt is evaporated and the resinous residue washed successively with water, dilute hydrochloric acid, and dilute alcohol; it is then dissolved in dilute alcohol containing hydrochloric acid, the *base* precipitated by sodium acetate, and crystallised from alcohol. It forms delicate brownish-yellow needles, melting at 221°, sparingly soluble in ether and petroleum spirit, easier in benzene and cold alcohol; its solutions show a yellow-green fluorescence. It sublimes in woolly needles, and gives, with concentrated hydrochloric or sulphuric acid, a green colour, dissolving, however, in glacial acetic or dilute mineral acids with a cherry red colour. It is isomeric with Witt's dimethylamidonaphthaeurodine (Ber. 21, 719). The *hydrochloride* and the *sulphate* form copper-glistening needles and the *nitrate* small bronze-coloured needles. The *platinohchloride* and *aurochloride* crystallise in red needles, the former being sparingly soluble in alcohol.

α-Dimethyl-amido-α-naphthalolazine—

prepared from toluenylenediamine [$\text{CH}_3 \cdot \text{NH}_2 : \text{NH}_2 = 1 : 3 : 4$], and benzene-azo-dimethylnaphthylamine, resembles the foregoing base, but is somewhat less soluble; it gives the same colour reaction with concentrated sulphuric acid, and forms brownish-yellow needles from boiling alcohol, melting at 230°. It sublimates in woolly needles with partial carbonisation. The *hydrochloride* and the *sulphate* crystallise in garnet-red glistening needles, easily soluble in alcohol, and the *nitrate* separates from alcohol in delicate needles, having a bronze shimmer. The *platinohloride* and the *aurochloride* form brownish-red needles.—A. R. L.

The Tinctorial Properties of the Nitrosohydroxyquinolines.
S. v. Kostanecki. Ber. 24, 150—156.

The author has pointed out (this Journal, 1888, 33 and 838; and 1889, 698) that *ortho*-nitrosophenols (quinoneoximes) are dyestuffs, and he has now extended his experiments to the corresponding quinoline derivatives.

Nitroso-p-hydroxyquinoline, $\text{C}_9\text{H}_7\text{N} \cdot (\text{O} \cdot \text{NOH})$ (Mathews, Ber. 21, 1886), crystallises from alcohol in yellow needles, carbonising at 180°; it dyes green with iron mordants, and brick-red with cobalt mordants. Its most probable constitution is $[\text{O} : \text{NOH} = 3 : 1]$.

Nitroso-o-hydroxyquinoline $[\text{O} : \text{NOH} = 1 : 4]$ is formed when *o*-hydroxyquinoline $[\text{OH} = 1]$ is dissolved in dilute soda with the addition of the theoretical quantity of sodium nitrite and the mixture poured into cooled dilute acetic acid, or when the hydroxy-derivative is dissolved in dilute hydrochloric acid (2 mols.) and sodium nitrite gradually added (compare Lippmann and Fleissner, Monatsh. 10, 794). The crude base has tinctorial properties, but this was found to be due to the presence of an isomeric by-product (probably an *ortho*-derivative), which is precipitated as a green lake on adding ferrous sulphate to the solution of the crude base in soda. The pure base crystallises from alcohol in thick yellowish needles, darkening below 220° and decomposing with evolution of gas at 245°; it possesses no tinctorial properties.

Amido-o-hydroxyquinolin—

prepared by reducing the foregoing with tin and hydrochloric acid, is identical with that obtained by Fischer and Renouf (Ber. 17, 1642); it forms a *sulphate* crystallising in needles, containing 2 mols. of water and melting at 110°. It possesses weak tinctorial properties.

Nitro-o-hydroxyquinoline—

identical with that obtained by Schmitt and Engelmann (Ber. 20, 2693), is formed when finely powdered nitroso-*o*-hydroxyquinoline (1 part) is added to cooled nitric acid sp. gr. 1.38 (4 parts); solid soda is added until the precipitated nitrate redissolves, and the base is thrown down by acetic acid. It dyes with iron mordants green, and with aluminum mordants yellow; it also forms a bright green lake with ferrous sulphate.

Dinitro-o-hydroxyquinoline—

identical with that of Bedall and Fischer (Ber. 14, 1368) is obtained by treating nitroso-*o*-hydroxyquinoline with boiling nitric acid; its tinctorial properties are weaker than those of the mononitro-derivative.

The author has learned from Nolting and Trautmann that *o*-hydroxyquinoline is itself a weak dyestuff. This work proves therefore that *ortho*-quinone-oxime derivatives of quinoline, like those of the aromatic hydrocarbons, possess tinctorial properties, and that the latter can also be brought about by the exchange of that atom of hydrogen in the benzene nucleus of quinoline, adjacent to the nitrogen atom of the pyridine nucleus, for hydroxyl or the isonitroso-group.—A. R. L.

Quinolinedioximines. S. v. Kostanecki and M. Reicher.
Ber. 24, 156—159.

As in certain dyestuffs the hydroxyl of the colour-producing groups may be replaced by the isonitroso-group, without the compound losing its tinctorial properties (compare Kostanecki, Ber. 22, 1351; this Journal, 1888, 698 and 699), it was to be expected that the dioxime obtained from nitroso-*o*-hydroxyquinoline (previous abstract) would also retain these properties, and this is found to be so.

Quinolinedioxime, $\text{C}_9\text{H}_5\text{N}(\text{NOH})_2$ $[\text{NOH} : \text{NOH} = 1 : 4]$, is formed when a solution of hydroxylamine hydrochloride is added to nitroso-*o*-hydroxyquinoline (previous abstract) mixed into a paste with water. It is boiled with sufficient alcohol to dissolve it, and after distilling off the latter, excess of soda is added, and the dioxime precipitated by acetic acid. It separates from alcohol in microscopic crystals decomposing above 200°. It dyes with iron mordants, in a bath acidified with acetic acid, intensely green to black, and with cobalt mordants faint brownish yellow; the colours are fast. On boiling with acetic anhydride, it yields a diacetyl-derivative, $\text{C}_9\text{H}_5\text{N}(\text{NO} \cdot \text{C}_2\text{H}_3\text{O})_2$, which crystallises in white needles, decomposing at 160°.

Quinolinedioxime $[\text{NOH} : \text{NOH} = 3 : 4]$ is obtained by adding an aqueous solution of hydroxylamine hydrochloride to finely powdered nitroso-*p*-hydroxyquinoline (previous abstract) suspended in alcohol, and boiling. After distilling off the alcohol, cold soda-lye is added until a clear solution results, from which the dioxime is then precipitated by acetic acid. It crystallises from alcohol in small needles, decomposing at 190°. It dyes faintly brown with iron mordants in a neutral bath, but its tinctorial properties are far less pronounced than those of the 1:4 isomeride. The *anhydride*, $\text{C}_9\text{H}_5\text{N}(\text{N}_2\text{O})$, crystallising from alcohol in long needles, melting at 134°, is formed when the dioxime is warmed with alkalis or acetic anhydride.—A. R. L.

Carbazole. G. Mazzara. Ber. 24, 278—281.

Benzoylcarbazole, $(\text{C}_6\text{H}_5)_2\text{N} \cdot \text{CO} \cdot \text{C}_6\text{H}_5$, is obtained by heating carbazole (1 mol.) and benzoic chloride (1 mol.) for about two hours at 160—170°. The mixture is then warmed with a weak solution of caustic soda, allowed to cool, filtered, and the solid mass purified by repeated recrystallisation from hot alcohol. It forms lustrous needles which melt at 98.5°, and is readily soluble in ether and glacial acetic acid but sparingly soluble in benzene and light petroleum. It is decomposed by alcoholic potash into carbazole and benzoic acid, a reaction which shows that the benzoyl group is attached to the nitrogen atom. As a further proof of the absence of a ketone the base was subjected to the action of hydroxylamine and phenylhydrazine. It is decomposed by the former into carbazole and benzamide whilst phenylhydrazine does not react with it.

Nitrobenzoylcarbazole, $(\text{C}_6\text{H}_5\text{NO}_2 \cdot \text{C}_6\text{H}_5)_2\text{N} \cdot \text{COC}_6\text{H}_5$, is formed by the action of nitric acid (sp. gr. 1.48) on benzoylcarbazole dissolved in glacial acetic acid. It crystallises in yellow lustrous plates, melting at 181°, dissolves in warm ether and benzene, but only sparingly in alcohol and light petroleum. It is not attacked by potash.

Mononitrocarbazole, $(\text{C}_6\text{H}_4 \cdot \text{C}_6\text{H}_3\text{NO}_2)\text{NH}$, is obtained by boiling benzoylnitrocarbazole with alcoholic potash in a reflux apparatus. It crystallises from alcohol in small scales which melt at 210°, is sparingly soluble in glacial acetic acid, chloroform, and benzene, and almost insoluble in ether and light petroleum.—D. R.

Syntheses of Carbazole. A. Blank. Ber. 24, 306.

The author has obtained carbazole synthetically by passing the vapour of orthamidodiphenyl over lime heated to dull redness.

Diphenylene, when similarly treated, gave amidocarbazole, a feeble base, the salts of which are readily decomposed.

It crystallises from water in small needles which melt at 238° and resemble benzidine in colour and lustre.—D. B.

A New Method of Formation of Soluble Indulines. Fischesser. Bull. Soc. Ind. Mulhouse, 1891, 48—51.

THE earliest known members of the class of induline dyestuffs are insoluble in water, and have either to be sulphated to render them soluble, or dissolved in alcohol, ethyl tartrate, or acetic, to enable them to be employed for dyeing or printing. Recently numerous methods have been discovered for the manufacture of indulines soluble in water. The chief of these methods may be summarised as follow: (1) The action of nitramines on the hydrochlorides of other monamines; (2) the action of amidazo-benzene on aniline and aniline hydrochloride, different proportions of these compounds being used from that used in the manufacture of insoluble indulines; the soluble induline obtained in this way has the formula $\text{C}_{24}\text{H}_{15}\text{N}_5$; (3) the use of secondary or tertiary amines in place of the primary amines previously used. The reaction of *p*-phenylenediamine with (4) amidazo-compounds; (5) azophenine; (6) *p*-phenylenediamine hydrochloride and nitrobenzene in the presence of ferrous chloride; (7) α -amidazonaphthalene or α -amidonaphthalene-azobenzene; (8) chloranil; (9) diamidazoxybenzene hydrochloride; (10) pheno- and tolu-saframines; (11) unsymmetrical triamidobenzene; (12) azobenzene or azotoluene; (13) induline, soluble in spirit, of the formula $\text{C}_{20}\text{H}_{12}\text{N}_5$; (14) *p*-diamidazoxybenzene; (15) induline, soluble in spirit, of the formula $\text{C}_{18}\text{H}_{11}\text{N}_5$; (16) induline, soluble in spirit, obtained by the action of diazotised benzidine on aniline; (17) the substance produced by the combination of diazobenzene with naphthylenediamine. (18) A soluble induline is formed along with other substances by heating together in aqueous solution the hydrochlorides of aniline and amidazo-benzene.

The new method discovered by the author consists in causing primary, secondary, or tertiary aromatic amines to react with the amidazo-compounds produced by the action of the diazo-derivatives of *o*-, *m*-, or *p*-nitraniline on *o*- or *m*-nitraniline, or with the diazo-amido-compounds formed by the combination of the diazo-derivatives of *o*-, *m*-, or *p*-nitraniline with *p*-nitraniline. In practice, these bodies are heated with ferrous and zinc chlorides, and according to the temperature of the reaction and the proportions of materials employed, grey, blue or violet dyes are produced. As an example, 250 parts of diazoamidodinitrobenzene (from *p*-diazonitrobenzene and *p*-nitraniline), 500 parts of aniline hydrochloride, and 575 parts of dimethylaniline hydrochloride, are heated with ferrous and zinc chlorides at 140° to 200° until a sample, on testing, dissolves in dilute hydrochloric acid with the desired shade of colour. The reaction is then interrupted, the mass dissolved in dilute hydrochloric acid, rendered alkaline with lime, and the unchanged bases removed by a current of steam. The free colour-base is washed with water, re-dissolved in dilute hydrochloric acid, and the dye salted out. It forms a black powder which is sparingly soluble in cold water, but freely so in hot, with a violet-blue colour. It yields blue-grey shades on cotton mordanted with tannic acid.—E. B.

Some Derivatives of Dimethylaniline. C. Lauth. Compt. Rend. 111, 886—888.

THE action of lead dioxide on dimethylaniline is essentially different from that of various other oxidising agents; with the latter, one of the methyl-groups is attacked, giving rise to the formation of Methyl violet, but with lead dioxide the

phenyl groups are oxidised with the production of tetramethylbenzidine. Several methods have been described for the preparation of tetramethylbenzidine from dimethylaniline, but the process with lead dioxide is distinguished by the rapidity and ease with which it gives an abundant yield of that base. To prepare tetramethylbenzidine by this method, 20 parts of dimethylaniline are dissolved in 120 parts of acetic acid at 8° B. and 160 of water, and 20 to 30 parts of lead dioxide are gradually added whilst the temperature is kept below 30° or 35°. The reaction is complete in 5—10 minutes. The product is filtered, washed with hot water, boiled with water to eliminate all traces of dimethylaniline, dried and purified by repeated crystallisation from light petroleum. The mother-liquors, after removal of the lead by sulphuric acid and neutralisation with ammonia, give a small quantity more of the base. The yield altogether is about 40 per cent. Oxidising agents, such as lead dioxide, ferric chloride, bichromates, atmospheric oxygen, &c., give with mere traces of tetramethylbenzidine an intense green colouration, which is noticeable when preparing that substance by the above method. When prepared by the action of a tolerably strong solution of ferric chloride on tetramethylbenzidine hydrochloride, the compound, whose presence causes this green colouration, has the constitution—

If an excess of a solution of ferric chloride at 45° B. be used, an orange-coloured ferric chloride double-salt is obtained. The zinc double-salt is sparingly soluble in saline solutions. All the salts of this compound are soluble in water; they are also soluble in alcohol and are precipitated by ether from solution in the same. The compound itself is extremely unstable, apparently existing only in the form of salts; it is decomposed by cold, and very rapidly by hot, water, the solutions being decolourised, and tetramethylbenzidine regenerated; alkalis form with it tetramethylbenzidine and hydrogen dioxide; it is decomposed by drying in vacuo; it is capable of dyeing, yielding on silk very pure shades of green, which, however, quickly disappear even when protected from air and light.—E. B.

Colour Reactions of Aromatic Amines. C. Lauth.

Compt. Rend. 111, 975—977.

See under XXIII., page 389.

PATENTS.

Colouring Matters Obtainable by the Combination of Tetrazoditolyl or Tetrazodidyl Salts with Alpha- and Beta-Naphthylamine or their Mono- and Disulpho Acids, and Process for the Manufacture of the same. H. J. Haddan, London. From the "Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 3803, March 24, 1885. (Third Edition.) 6d.

This specification has already been abstracted (this Journal, 1886, 96).—T. A. L.

The Manufacture of Sulphonated Thionines. S. Pitt, Sutton. From L. Casella and Co., Frankfurt-on-the-Maine, Germany. Eng. Pat. 4596, March 24, 1890. 6d.

A process for obtaining blue to greenish-blue dyestuffs which dye animal fibres from an acid bath. The following quantities are given for the formation of a colouring matter, which dyes wool the same shade as indigo carmine. 30 kilos. of benzyloethyl-*p*-phenylenediamine sulphonic acid are dissolved in 300 litres of water and mixed with a solution containing 30 kilos. of aluminium sulphate and 26 kilos. of sodium thiosulphate. The whole is then oxidised with 10 kilos. of potassium bichromate forming *cr*visulphobenzyl-*p*-phenylenediamine thiosulphonic acid, and giving a colourless solution. A dilute solution of

29 kilos. of benzylethylaniline sulphonic acid is then added, and the whole oxidised with 30 kilos. of potassium bichromate, boiled for a short time, and zinc chloride added. The dyestuff forms a dark blue solution, and after filtering is precipitated by salt. The benzylethylaniline sulphonic acid can be replaced by mono- or dimethylaniline or mono- or diethylaniline or *o*-toluidine with the formation of similar colouring matters.—T. A. L.

Production of Ethyl Ether of Cinnamic Acid. O. Imray, London. From the "Farbwerke vormals Meister, Lucius, und Brüning," Hoechst-on-the-Maine, Germany. Eng. Pat. 1946, March 29, 1890. *Ad.*

The method hitherto employed for obtaining cinnamic and ethyl ether has been the etherification of cinnamic acid. The ether can, however, be obtained directly from benzaldehyde by the action of acetic ether in presence of metallic sodium. 45 kilos. of acetic ether and 1.15 kilos. of sodium (in small pieces) are kept cool by means of iced water, and 10.65 kilos. of benzoic aldehyde allowed to run in slowly. When the whole of the sodium has disappeared acetic acid is added corresponding to the sodium taken, and on dilution with water the ether separates. After drying with calcium chloride the acetic ether is distilled off on the water-bath, and the cinnamic ethyl ether is rectified, distilling at about 260—275° C.—T. A. L.

Manufacture of Azo Colouring Matters Derived from Azoguanines. J. Imray, London. From "La Société Anonyme des Matières Colorantes et Produits Chimiques de St. Denis" and A. F. Poirrier and D. A. Rosenstichl, Paris, France. Eng. Pat. 5736, April 15, 1890. *Ad.*

A NITRO-AMINE is diazotised and combined with a phenol or amine, hydroxy-derivative or sulphonic or carboxylic acid, and the azo compound thus obtained is reduced in an alkaline solution with zinc-dust, glucose, arsenious acid or other reducing agent. Para-nitroaniline is diazotised in an acid solution and combined with naphthol disulphonic acid. This colouring matter dyes wool red, but not cotton. 55 kilos. are dissolved in 2,750 litres of water and 76 litres of caustic soda-lye of 40° B. The solution is heated to 80°, and 17.5 kilos. of glucose in 350 litres are added with constant agitation. At the end of an hour the new colouring matter is precipitated by the addition of salt, and dyes un mordanted cotton blue from an alkaline bath. (See also Eng. Pat. 1579 of 1890; this Journal, 1891, 131.)—T. A. L.

The Preparation of New Sulphonic Acids for the Production of a Blue Colouring Matter for Cotton. S. S. Bromhead, London. From "Die Chemische Fabrik Grunau, Landshoff und Meyer," Grunau, Berlin, Germany. Eng. Pat. 6195, April 23, 1890. *Ad.*

SODIUM NAPHTHIONATE is heated in a current of carbonic acid in a horizontal cylinder provided with an agitator to a temperature of from 220—240° C. until a test dissolved in water no longer shows a violet blue fluorescence in a dilute solution, when the melt is dissolved in water and precipitated with sulphuric acid. The new α -naphthylamine sulphonic acid formed, gives a diazo compound crystallising in greenish-yellow scales, and is converted on boiling with dilute sulphuric acid into an easily soluble α -naphthol sulphonic acid which yields a dichloronaphthalene melting at 35° C. On sulphonation with four parts of fuming sulphuric acid containing 10 per cent. of anhydride the α -naphthylamine sulphonic acid is converted into a new α -naphthylamine disulphonic acid easily soluble in water, but sparingly so in dilute sulphuric acid. When the sodium salt of this acid is heated in an autoclave with caustic soda and water for 20 hours to about 260° C. a new amido-naphthol sulphonic acid is produced, which on combination with tetrazodiphenyl in an acetic acid or alkaline solution yields a blue colouring matter which dyes un mordanted cotton.—T. A. L.

Manufacture of Nitrated Colouring Matters. J. Imray, London. From "La Société Anonyme des Matières Colorantes et Produits Chimiques de St. Denis," Paris, France. Eng. Pat. 6486, April 28, 1890. *Ad.*

CERTAIN colouring matters such as Fuchsin, Dimethylaniline violet, and Methylene blue, are treated with a mixture of sulphuric and nitric acids. The shades of the dyestuffs produced do not differ greatly from the original colouring matters, but "all these products have the advantage of not colouring the light parts of a design produced by removal of the tannin mordant, and they resist soap and light at least as well as the colouring matters whence they are derived."—T. A. L.

Improvements in the Manufacture of Colouring Matters. C. D. Abel, London. From the "Actien Gesellschaft für Anilin Fabrikation," Berlin, Germany. Eng. Pat. 6932, May 5, 1890. *Ad.*

By the action of one molecule of tetrazoditoly on one molecule of α -naphthylamine the following compound is formed—

This, by treatment with nitrous acid, can be converted into a tetrazo compound and combined with phenols, amines, or their sulphonic or carboxylic acids. The bodies obtained dye un mordanted cotton violet to blue shades which are fast to light. 10.9 kilos. of tolidine are converted into the tetrazo compound and added to a solution of a salt of 7.5 kilos. of α -naphthylamine. After standing some time the mixture is acidulated with hydrochloric acid and diazotised with sodium nitrite. The tetrazo compound thus obtained is combined with 40 kilos. of the sodium salt of α -naphthol disulphonic acid (Eng. Pat. 4625 of 1888; this Journal, 1889, 280). After standing some hours the solution is boiled and the dyestuff precipitated with salt, filtered and dried. It dyes un mordanted cotton bluish-violet. If 17.1 kilos. of diamididine be substituted for the tolidine a colouring matter is obtained which dyes cotton a bluish-green.—T. A. L.

Production of New Basic Blue Colouring Matters. S. Pitt, Sutton. From L. Casella and Co., Frankfurt-on-the-Maine, Germany. Eng. Pat. 6946, May 5, 1890. *Ad.*

SECONDARY amines of the fatty series, as for instance, dimethylamine and diethylamine, combine with colouring matters of the oxazine class such as New blue, Muscarine, Galloxyamine to form bases which on oxidation give blue colouring matters of purer and greener shades. 32 kilos. of dimethylamidonaphthophenoxazine chloride (New blue R) are mixed with an aqueous solution containing 30—40 per cent. of dimethylamine. A substance is formed sparingly soluble in water, but soluble in dilute hydrochloric acid. This is oxidised by passing air through for several days at 15° C. until the mass has become dry. The oxidation is finished when a test is completely soluble in hot water. The whole is then dissolved in 1,000 litres of water, neutralised with hydrochloric acid, filtered, cooled to 15° C., and precipitated with salt. The colouring matter separates in green needles and dyes cotton mordanted with tannin a greenish-blue fast to soaping and light, and dyes wool a deep blue from a neutral or acid bath.—T. A. L.

Improvements in Treating Alizarin Blue for the Obtainment of New Compounds thereof, and Alizarin Blue S. J. Y. Johnson, London. From the "Badische Anilin und Soda Fabrik," Ludwigshafen-on-the-Rhine, Germany. Eng. Pat. 8303, May 28, 1890. *Ad.*

According to Eng. Pat. 3603 of 1881, Alizarin blue is converted into Alizarin blue S by treatment with an alkaline bisulphite or by passing sulphurous acid gas through an aqueous solution of an alkali containing Alizarin blue in suspension. According to the present invention the alkaline bisulphites are to be replaced by the sulphite of an organic

base such as aniline. It has also been discovered that Alizarin blue itself, when suspended in water and treated with sulphurous acid gas, forms a new compound, Alizarin blue sulphite, which, on treatment with sodium acetate or other suitable alkaline compound, gives Alizarin blue S. The following proportions are given for preparing Alizarin blue S according to the first method. A solution of aniline sulphite of sp. gr. 1.16 is prepared by mixing aniline with water and saturating the mixture with sulphurous acid gas. One hundred parts by weight of this are mixed with 100 parts of Alizarin blue paste containing 20 per cent. of the dry substance. After standing a few days at the ordinary temperature the colour of the paste changes to brownish red. It is then filtered off, dissolved in water, and sodium acetate added, which precipitates Alizarin blue S together with some of the double sulphite which may escape decomposition, but does not interfere with the dyeing properties of the product.

—T. A. L.

Processes for the Manufacture of Colouring Matters. T. Peters, Chemnitz, Germany. Eng. Pat. 21,205, December 30, 1890. 6d.

A NUMBER of sulphonated naphthalene derivatives are specified which on heating with aniline and its hydrochloride yield substances which on sulphonation are dyestuffs. The following are some of the derivatives mentioned: Meldola's nitroso- β -naphthol-monosulphonic acid, nitroso- β -naphthol-disulphonic acid R. and G., benzene-azo- β -naphthol-monosulphonic acid, "benzene-azo-naphthalidin-sulphonic acid," &c.—T. A. L.

Manufacture of New Colouring Matters. J. C. L. Durand, D. E. Huguenin, and A. J. J. d'Andiran, of "La Société L. Durand, Huguenin, et Cie," Bâle, Switzerland. Eng. Pat. 583, January 12, 1891 (Internat. Conv. June 13, 1890.) 4d.

AN extension of Eng. Pat. 11,848 of 1889 (this Journal, 1890, 610), and of Eng. Pat. 15,360 of 1889 (this Journal, 1889, 981). The colouring matters obtained according to the previous patents are heated with aniline or its homologues, the naphthylamines, or with *p*- or *m*-phenylenediamine, or with a mixture of these amines, to between 100°–200° C. The colouring matters described in the above-mentioned patents dissolved in sulphuric acid with a blue colour, whereas the new substances dissolve with a cherry-red colour. On sulphonation they yield colouring matters which dye wool and silk blue from an acid bath.

—T. A. L.

V.—TEXTILES: COTTON, WOOL, SILK, Etc.

PATENTS.

Improvements in the Manufacture of Artificial Silk Filaments, and in Apparatus for that Purpose. H. de Chardonnet, Paris, France. Eng. Pat. 1656, January 30, 1890. 11d.

THIS invention relates to the process and apparatus for spinning artificial silk from nitro-cellulose, dissolved in a mixture of equal volumes of ether and alcohol, to which is afterwards added some more alcohol (see this Journal, 1887, 139; 1888, 206; 1889, 539 and 611; and 1890, 286). The machine employed has a number of tubes with capillary nozzles, placed in water jackets open at the top, the water being in some cases charged with glutinous matter or with substances which render the fibres less combustible. The solution of nitro-cellulose is supplied to the tubes under considerable pressure, which causes a fine stream of the solution to issue from each of the capillary nozzles. By the influence of the water of the jacket this stream becomes a solid fibre or thread, which is wound on to bobbins, several

fibres usually being taken together, thus producing compound fibres. When full the bobbins are automatically exchanged for others. They are within a casing through which passes a current of air of 50° C., which carries with it the vapour of the solvents. These vapours are condensed or absorbed by different liquids.—H. S.

Improvements in Calendering Textile Fabrics and in Apparatus therefor. J. Haddow, Manchester. Eng. Pat. 4416, March 21, 1890. 6d.

FRICTION calenders are usually fitted with three bowls, and the finish is obtained by a single friction process. By this method, however, the machine is often rendered inoperative, if the bowl which gives the finish is damaged by folds or creases in the fabric. The patentee therefore divides the finishing into two operations by the addition of a fourth bowl, hereby eliminating folds and creases, obtaining a second and better finish for the fabrics, and keeping the machine in a much better state.—H. S.

Improvements in the Treatment of, or Finishing of, Manufactured or partially Manufactured Materials from Cotton or other Cellulosic Fibres. H. A. Lowe, Heaton Moor. Eng. Pat. 4452, March 21, 1890. 6d.

VEGETABLE fabrics, such as cotton and flax yarns and cloth, are immersed from 1 to 15 minutes, according to the texture of the material, in a solution of caustic soda from 25° to 75° Tw. The shrinkage which usually occurs in this process is obviated by stretching the materials during or after this treatment with caustic soda. Then they are thoroughly rinsed in warm water, and after that they may be further treated with bleaching compounds or dilute acids, in order to remove any colour and to neutralise any remaining traces of the alkaline bath. The caustic soda may be recovered from the wash-water by concentration. The materials thus treated are said to possess the advantages of being considerably stronger, of having a more regular, close and glossy appearance, and of taking many dyes and colouring matters more readily and economically.—H. S.

Improvements in the Treatment of Vegetable Materials for obtaining therefrom Textile Fibres for Spinning Purposes and the like, and Cellulose for Use in the Manufacture of Paper. A. J. Boulton, London. From G. Rudel, Dresden, Germany. Eng. Pat. 18,018, November 8, 1890. 4d.

THE methods adopted for the production of cellulose from wood, straw, &c. are subject to the drawback that in dissolving the incrusting substances the cellular tissue is destroyed to such an extent as to render the fibres unsuitable for spinning. The patentee claims that by his treatment the incrusting substances are dissolved, whilst the fibres preserve their natural length and firmness. To effect this the vegetable materials are boiled in a mixture of water and calcium-, barium-, strontium or magnesium sulphide from 1 to 10 hours, at a pressure from 2 to 10 atmospheres. The amount of the chemicals varies according to the nature of the materials. The sulphides mentioned may be mixed with carbonates or hydrates of alkalis. The fibres thus obtained are washed, and those suitable for spinning separated from the short ones, the latter being further treated to produce pulp for paper manufacture.—H. S.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

The so-called "Ash-Free" Egg Albumen. E. Harnack.
Ber. 23, 3745—3752.

In order to obtain egg albumen free from inorganic salts and from the basic salts with which it is combined, it is cut up fine and first treated with an excess of very dilute acetic acid to separate the globulines; the acid must not be too strong or the albumen will be coagulated. This acid solution is filtered and the filtrate made alkaline by addition of a cold saturated solution of sodium carbonate. A cold saturated solution of copper sulphate is then added, when a light green precipitate of a copper albuminate is thrown down. This, after washing, is dissolved in caustic alkali, and the resulting dark violet-coloured liquid again treated with dilute acetic acid when the copper albuminate again separates. This procedure is repeated several times, and the quantity of copper contained in the precipitate is found to decrease on each treatment until it reaches about 1.35 per cent. When this is the case the precipitate, whilst still moist, is treated with water and strong caustic potash solution, when a thick dark violet-coloured liquid results, from which the albumen is precipitated by the addition of hydrochloric acid. This precipitate when washed free from acid forms the "ash-free" albumen. It dissolves in boiling water to a clear solution, which reddens neutral litmus paper and is not precipitated by the addition of alcohol; mineral acids and neutral salts precipitate it at once, but the precipitation by the latter is prevented by the presence of caustic alkalis. The aqueous solution on prolonged boiling gives the peptone reactions. When placed in distilled water, this ash-free albumen swells up before passing into solution. Organic acids do not precipitate it from aqueous solution, not even tannic acid. When precipitated from aqueous solution by mineral acids, or by neutral salts, the albumen itself can be recovered unchanged by washing out the precipitants, and is then as before soluble in water; it has not been in any way coagulated. When left to itself the moistened albumen shows no tendency to ferment, but dries up to a yellow, brittle, transparent mass; even on addition of pancreatic ferment it undergoes no change.

These are the chief distinctions of the "ash-free" albumen from ordinary albumen, in which the former is combined with bases.—C. A. K.

Note on the Fixation of Colours by Steaming. Rosenstiehl.
Bull. Soc. Ind. Mulhouse, 1890, 401—419.

In topical styles of calico printing certain colours are used, which after being fixed by steaming in the usual way, require to be developed by oxidation, which is generally effected by chroming. But this operation, although eminently useful for these colours, greatly injures others, such as Alizarin reds and pinks, Persian berry yellows, &c. The author discovered in 1874 that by a modification of the ordinary method of steaming, it was possible at the same time to fix and oxidise the colours requiring oxidation, notably, Prussian blue, Logwood black, and other wood colours, without harming the colours which are injured by chroming. The modification in question consists in introducing hot air along with the steam into the steaming apparatus. The first attempts to do this were unsuccessful. Although the temperature of the mixture of air and steam was 109—114°, the wet bulb thermometer indicating 73—78°, the colours were not fixed, not even the pigment colours, which is a curious fact, inasmuch as albumen in aqueous solution is coagulated at 60—70°. The reason of this was that there was too much air and consequently too little steam in the steaming vessel.

It was found that a mixture of air and steam is capable of fixing colours only when its saturation temperature is at least 91°. With a saturation temperature of 88°, for example, the fixation is very imperfect. The presence of air prevents the saturation temperature approaching very closely to, or becoming 100°, but 94—96° may be readily attained. Without air, it is of course easy to obtain a

saturation-temperature of 100°, or higher than this, in apparatus arranged to work under pressure. But steam is too moist when fully saturated, that is when its temperature is the same as its saturation-temperature; the former must be at least 4° higher than the latter. In the author's experiments it was frequently 6°, 8°, or even 10° higher. The best limits, however, are 91 to 100 for the wet bulb thermometer against 95 to 106 on the dry bulb instrument. It is unnecessary to force the hot air into the steaming vessel by a fan or other mechanical appliance, all that is necessary, since there is no pressure inside the vessel, being to mix the heated air in properly regulated amount with the steam supply.

To ascertain the degree of humidity in the steaming vessel, weighed wet and dry strips of calico may be conveniently used instead of thermometers. The moist strips of calico, under the most suitable conditions of steaming, lose at most 50 to 120 grms. per square metre per hour. The dry strips gain at most 5 to 10 grms. per square metre per hour, and must on no account lose weight.

This system, which is described in considerable detail in the original, enables an economy to be realised varying from $\frac{2}{3}$ to $\frac{1}{10}$ of the fuel used.—E. B.

Chromium Fluoride. T. Stricker. Bull. Soc. Ind. Mulhouse, 1890, 420—421.

At the request of the Chemical Committee of the Industrial Society of Mulhouse, the author has determined the value of chromium fluoride as a mordanting salt for cotton, as compared with the chromium salts in use for that purpose. Printed with alizarin, the fluoride was found to give paler and yellower shades than did equivalent amounts of the basic acetate, $\text{Cr}_2(\text{C}_2\text{H}_3\text{O}_2)_4(\text{OH})_2$, prepared by dissolving chromic hydrate in the calculated amount of acetic acid.

In another experiment a suitably thickened solution of the fluoride was printed. The printed cloth, after being dried, was divided into two parts; one part was passed through a boiling, concentrated solution of sodium carbonate in order to fix the mordant; the other was steamed before being similarly treated. A second fent was printed with an equivalent solution of chromium acetate and treated in the same way. The various fents were then dyed. The colours obtained were much the same in all cases, the greatest difference being observable in the fents printed with chromium acetate, the steamed fent showing a deeper shade; with the fluoride, steaming had very little influence. The shades produced were compared with those obtained on cotton mordanted with chrome by the alkaline method, a solution containing the same proportion of chromic hydrate, as was used in the printing trials, being employed. The colours on the alkaline mordant were found to be brighter than those on the mordants deposited from the fluoride and acetate; they also discharged better. The colours on the acetate-mordant discharged better than those on the fluoride-mordant.

The fluoride possesses no advantage in the matter of cost.—E. B.

A Reserve for Basic Coal-Tar Dyes. M. Prud'homme.
Bull. Soc. Ind. Mulhouse, 1890, 549—551.

The author finds that the addition of common salt to the tartar emetic reserve-colour suggested by him (this Journal, 1888, 565) is an improvement. This is based upon an observation made by Juste Koechlin, namely, that alkaline chlorides form with tartar emetic very soluble double salts. Two examples are given of the mixing of the reserve-colour:—

	Parts.	Parts.
Tartar emetic	300	300
Common salt	158	210
Water	1,000	1,000
British gum	700	700

The common salt is directly useful, also, in precipitating the colouring matter, which is brought into contact with it, and thus aids the tartar emetic, whose office is to precipitate the tannic acid of the printing colour, the colour-lake being formed superficially and so prevented from penetrating the fibre. In the case where the reserve has to resist at the same time a dark ground and a pale pad-shade, it is advantageous to add a certain amount of tannic acid to the pad colour in order to avoid "swelling" of the reserve pattern.

After steaming for an hour, the pieces are passed through a bath of tartar emetic, washed with hot water for half an hour, and lightly soaped.—E. B.

A Method of Preserving Printers' Soap-baths. E. Jaquet. Bull. Soc. Ind. Mulhouse, 1890, 551—552.

THE chief cause of the rapid soiling of soap-liquors, which takes place during the soaping of printed calicoes, is the solution from the cloth of Methylene blue and other dyes, fixed with tartaric acid. Methylene blue, in particular, would, if the baths were not frequently or continuously renewed, soil the alizarin pinks and reds, converting the same into clarets and chocolates. The colours may be preserved and the baths kept tolerably clean by the addition to the latter of precipitated tannate of antimony, since this compound possesses more affinity for the basic dyes than do the alizarin lakes. The method has been used on the large scale for upwards of a year with satisfactory results, the soap-baths requiring less frequent renewal than usual. The author hopes to find means of precipitating in a similar manner the other colouring matters which find their way into the soap-liquor.—E. B.

Proceedings of the Industrial Society of Mulhouse. Meeting of June 18, 1890. Bull. Soc. Ind. Mulhouse, 1890, 54—56.

Prud'homme contributed a memoir on the reactions of ferrieyanides. Ferrieyanides in the presence of alkalis exert an oxidising action, as was discovered by Mercer, who applied the reaction in calico-printing for discharging indigo. It is not generally known that at the boil neutral solutions of ferrieyanides decolourise indigo, acid ferrieyanides being formed and hydrogen and oxygen evolved as in the equation—

A mixture of a ferrieyanide and an alkaline chlorate gives quite as good results, when printed on indigo-dyed cloth and steamed, as the mixture of ferrieyanide and alkaline carbonate or bicarbonate, recommended by Jeanmaire. Scheurer, in 1878, discovered that the acetates of certain metals (calcium, magnesium, zinc, lead, &c.) could replace the alkaline carbonate or bicarbonate in Jeanmaire's process. Again, the firm of Koechlin Bros. discovered that indigo was dischargeable by a mixture of potassium ferrieyanide and lead nitrate, the action taking place at 30°—35° on ageing the printed cloth. Prud'homme finds that potassium ferrieyanide is decomposed by metallic copper, potassium ferrieyanide and potassium copper ferrieyanide being formed. Iron yields in similar manner a white precipitate of potassium ferrous ferrieyanide, $K_3Fe(FeC_6N_6)_2$, which soon becomes blue on exposure to the air. Lead reacts energetically with potassium ferrieyanide, the lead monoxide which is first formed becoming converted into lead dioxide—

Potassium chromate and ferrieyanide react with formation of bichromate and ferrieyanide and liberation of oxygen. Nitroprussides may be prepared by the action of alkaline nitrites on ferrieyanides. A strong solution of alkaline nitroprusside is obtained by treating potassium ferrieyanide with a solution of the salt (sodium hydroxylamine-disulphonate), obtained by the action of sodium bisulphite on sodium nitrite. A mixture of sodium nitrite, sodium thio-sulphate, and potassium ferrieyanide, when boiled some

time, also yields nitroprusside along with a brown insoluble compound, which dissolves in strong hydrochloric acid and gives a precipitate of Prussian blue on the addition of water, ferric chloride remaining in solution.—E. B.

A New Method of Formation of Manganese Bronze Colour. J. Dépierre. Bull. Soc. Ind. Mulhouse, 1891, 36—37.

THE cloth is passed through a neutral solution of manganese chloride (4 parts in 10 parts of water), dried, and the bronze is developed by a passage through a bath containing, in 20 parts of water, 1 part of potassium permanganate and 0.6 part of sodium carbonate. This "raising" bath is kept at a temperature of 35°, and the cloth immersed in the same for 40 to 50 seconds. To obtain even shades, the use of a "chloring box" is recommended, the apparatus being left empty, to remove the disengaged carbonic acid. The passage through the empty chloring apparatus may be beneficially followed by a passage through another steam chloring-box, using bleaching solution at 1.5° B. The cloth is then well rinsed and dried. The chief reaction taking place in this method of production of manganese bronze is expressed by the following equation—

The bronze obtained in this way discharges better than that produced by the old method.—E. B.

Report on a New Method of Formation of Manganese Bronze Colour. A. Frey. Bull. Soc. Ind. Mulhouse, 1891, 38.

THE author, who has been requested by the Industrial Society of Mulhouse to report on Dépierre's process (see preceding abstract), confirms the statements of that chemist regarding the advantages of the new method, but adds that the cost of the bronze is slightly higher than that of the bronze produced by the ordinary process. Frey recommends the temperature of the fixing-bath to be kept at about 40°, since the permanganate, in the proportion used, is not entirely soluble below that temperature.—E. B.

Compound Mordants. Prud'homme. Bull. Soc. Ind. Mulhouse, 1891, 39—47.

VAUQUELIN observed that magnesia, when precipitated along with alumina, had the property of rendering the latter insoluble in caustic alkalis. Later, H. Koechlin drew attention to the advantage of using an alkaline solution of zinc oxide for the fixation of mixed or compound mordants consisting of chrome or alumina with magnesia or lime, triple mordants being thus produced. The author finds that the property of forming with alumina a compound mordant insoluble in caustic alkalis is not restricted to magnesia, but is shared by other metallic oxides. He has also ascertained that other oxides than alumina, which separately are soluble in caustic alkalis, yield, as alumina does, compound mordants insoluble in the same.

An arrangement for the purposes of comparison and study of the common metals in two groups, first, those whose oxides are insoluble in caustic alkali, namely, Mg, Ca, Mn, Fe, Ni, Co, Cu, Sr, Ag, Cd, Ba, Hg, Pb, Bi, and U, and second, those whose oxides are soluble in excess of caustic alkali: Al, Si, P, V, Cr, Zn, As, Mo, Sn, Sb, and W, is not satisfactory. Certain elements, for instance, form two oxides belonging to different groups. Others, such as lead, form oxides which are soluble only in a large excess of alkali; and lastly, the oxides of two metals of the same group, zinc and tin, form together a compound mordant which is insoluble in caustic soda. This zinc-stannic mordant, in fact, resists the friction which occurs during the operation of dyeing even better than the magnesium-stannic mordant, the latter, probably on account of its gelatinous condition, being largely detached from the fibre during that operation. It is possibly due to their being in such a gelatinous condition, too, that the sesquihydrates of iron, aluminium, and chromium do not, when alone, act as satisfactory mordants.

Metallic Hydrates.—The quantity of caustic soda required for the solution of chromic hydrate corresponds with the formation of the compound $\text{Cr}(\text{ONa})_3$. This compound is, however, very unstable, its solution soon gelatinising, the action being probably analogous to that which takes place with a solution of zinc hydrate in caustic soda, where the zinc enters into solution as disodium zincate, $\text{Zn}(\text{ONa})_2$, but soon separates out as monosodium zincate, $2\text{ZnO} \cdot \text{Na}_2\text{O}$.

When alumina is dissolved in the minimum amount of caustic soda, there is formation of a compound of the formula $\text{Al}_2(\text{OH})_4(\text{ONa})_3$ or $2\text{Al}_2\text{O}_3 \cdot 3\text{Na}_2\text{O} \cdot 3\text{H}_2\text{O}$. Commercial sodium aluminate, made from bauxite, is of the same composition, but anhydrous. It is interesting that Rosenstiehl, in his analyses of the ash of the Turkey-red lake, found that the aluminium was present in the proportion of four atoms to three atoms of calcium, the real Turkey-red mordant, consequently, being of the formula, $2\text{Al}_2\text{O}_3 \cdot 3\text{CaO}$, or $2\text{Al}_2\text{O}_3 \cdot 3\text{CaO} \cdot 3\text{H}_2\text{O}$.

Reciprocal Action of Oxides.—In H. Koechlin's method of mordanting for St. Denis Red (this Journal, 1889, 703), cobalt and nickel oxides may with advantage be used instead of the magnesia employed in that process, faster and more solid shades resulting.

The arsenious oxide used in the mordant printing colour for dyeing alizarin chocolates, which Scheurer finds can be replaced by phosphorous acid (this Journal, 1888, 121), may also be replaced by the trioxides of bismuth and antimony, the last-named oxide especially, which is applied in the form of antimonious chloride, being of technical value in this respect.

The use of such assistants in mordanting for dyed alizarin chocolates gives rise in all cases to the production of compound mordants.

Compound mordants are produced in the operations of dunging with chalk, silicates, phosphates, stannates, zincates, &c. The basic sulphates of iron and aluminium may also be considered as compound mordants.

Copper salts, which are generally looked upon as merely assisting the ageing of the chocolate mordant, are of use solely in so far as the copper oxide contained in them becomes deposited on the fibre, forming a compound mordant.

Zinc nitrate, again, the hygroscopic action of which renders it useful in mordanting for Alizarin red, is directly serviceable in forming zinc aluminate in the dunging process. The same operation causes the formation on the fibre of aluminates of tin, which is produced from the stannous chloride used in conjunction with the aluminium mordanting salt, ageing alone but very imperfectly effecting this result.

All metallic oxides possess mordanting power, provided they are suitably combined with at least one other oxide; thus, the oxides of magnesium and zinc, separately, are absolutely devoid of dyeing power, but combined they constitute a very satisfactory mordant for alizarin. On the other hand, single metallic oxides do not exist. A double mordant, again, although to some extent capable of dyeing, may still require a further addition to enable it to dye properly; thus, the compounds of the oxides of iron and phosphorus, arsenic, antimony, or bismuth, dye very poorly without lime, or a similar oxide, in further combination with them. The best mordants are the compounds of such sesquioxides as Al_2O_3 , Cr_2O_3 , Fe_2O_3 , with protoxides.

Relations to the Periodic System.—In order to determine the influence of the oxides of one group of metals on the mordanting character of a given oxide of another group (iron, aluminium, &c.), two methods were used, namely, dye tests and precipitation of the colouring-matter as a lake. It is noteworthy that, as regards the colour-effect, the two methods may give widely different results, so that, with the same mordant and colouring matter, the shade obtained by one method may be, for example, the bluest obtainable from that particular colouring matter, by the other method it may be the reddest obtainable.

In the first group of elements, K yields redder shades than Na, Cu redder shades than Ag. Similar relations obtain in the second group between Ca and Mg, also with Zn and Cd. With the group Mg, Zn, Cd, there is an irregular progression in the shades yielded by these elements respectively, from

blue to red; Zn yields redder shades than Cd; Cd bluer shades than Mg; the middle element of the trio, Zn, appears to possess the maximum colouring power. In the second group, again, Ca, Sr, and Ba exert a regularly decreasing or increasing influence on the colour, that is, they cause the shade to pass from red to blue, or *vice versa*.

As regards the third group, the author conjectures that Ga and In will yield redder shades than Al does.

In the fourth group, Si gives redder shades than Sn, which yields yellow or orange shades.

In the next group As shows a greater bluing action on Alizarin purples than P or Sb; Bi produces even redder shades than P and Sb. With the lakes produced by the precipitation method the opposite is the case.

Cr, Mo, W, and V, in the sixth group of elements, produce an irregular series of colours, similarly to Mg, Zn, and Cd, this being probably due to the fact that these four elements form part of two trios, consisting of Cr, Mo, and an unknown element, and a second unknown element with W and V. Cr is dyed with alizarin a dull red, V a purple-blue. The colouring effects of Cl, Br and I, of the seventh group, are observable in the class of Eosins.

With regard to the colour-reactions of the various periods of elements, it is observed that Mg, Cu, and Ag do not yield such red lakes as Al, Zn, and Cd do, and that Si gives redder lakes than Al. Again, Sn yields redder lakes than Cd and Sb, which are placed in the table at its right and left respectively, and than Hg, Pb and Bi, which give bluer shades. Further, Pb gives redder shades than Hg and Bi.

The maximum colour-producing (reddening) effect appears, therefore, to be possessed by the members of the fourth group, on both sides of which the elements in the same periods graduate, in the shades they yield, towards blue, such gradation being least shown by the members of the seventh period. The element placed in the middle of this period, and, in fact, in the centre of the table, Sn, gives yellow and orange shades.—E. B.

Lactic Acid and Lactates in Textile Colouring. A. M. Norton and H. C. Tuttle. *Technology Quarterly*, 3, 287—291.

SUGGESTIONS have frequently been made regarding the use of lactic acid in textile colouring, but hitherto it has not been able to compete in price with tartaric and citric acids, whilst the cheaper qualities have not been sufficiently free from impurities. A suitable acid has been recently produced at a lower cost, and the experiments described were made with it. It contained about 43 per cent. of lactic acid, and was nearly colourless.

The impurities present were calcium sulphate and a faint trace of iron.

Amongst the experiments made in wool-dyeing the following were of exceptional interest. As a substitute for tartar, an acid potassium lactate was prepared by half neutralising the solution with potassium carbonate. Samples of wool were mordanted with the following proportions:—

	Per Cent.
Potassium bichromate.....	2.5
Tartar.....	2.5

also with

Potassium bichromate.....	2.5
Acid potassium lactate.....	2.5

The samples were then dyed with alizarin. The sample mordanted with acid lactate gave a decidedly heavier shade. Samples were mordanted with—

	Per Cent.
Potassium bichromate.....	2.5
Oxalic acid.....	1.0

also with

Potassium bichromate.....	2.5
Lactic acid.....	1.0

After dyeing with alizarin, the sample mordanted with lactic acid was much deeper in shade, than in the first case.

The most striking results were obtained with tin, the proportions used being—

	Per Cent.
Tin crystals	10
Tartar.....	10
and	
Tin crystals	10
Acid lactate.....	10

On dyeing with alizarin the colour obtained with tartar was the well-known reddish orange, while the lactate shade was a very brilliant yellowish red of great beauty, such as it has hitherto been very difficult to produce on wool with alizarin. With alum and lactate as a mordant, the alizarin shade obtained was very much bluer, and somewhat heavier than that obtained with tartar. That the heavier shades obtained with lactic acid were due to the more abundant fixation of the base was proved in the following experiments. Three baths were prepared with equal quantities of alum in each, but with equal weights of tartar, acid potassium oxalate and acid potassium lactate respectively. On mordanting equal weights of wool the results were—

	Tartar.	Oxalate.	Lactate.
Alumina fixed	63.5	71.8	80.0
Alumina remaining in the bath	36.5	28.2	20.0
Similar experiments with ferrous sulphate gave—			
Iron fixed.....	40.4	47.5	60.2
Iron remaining in the bath ...	59.6	52.5	39.8

On dyeing the samples with alizarin the results agreed with the figures furnished by the analysis, except that the difference in favour of the lactate mordant was more pronounced.

The results obtained on wool with dye-woods were much less favourable to the lactate mordants. With 20 per cent. of logwood, the blue obtained was not so bright or heavy as with the tartar, and in the case of bark liquor the shade was a dull reddish yellow. With fustic or tin mordants, the lactate gave a purer yellow than the tartar.

For use in cotton-dyeing a double lactate of antimony and potassium was prepared by dissolving hydrated oxide of antimony in acid potassium lactate to saturation, and evaporating the clear solution to dryness. In all the experiments the cotton was worked for one hour in a solution of 25 per cent. of sumach, and then treated with a solution containing 2 per cent. of the double lactate in the one case, and with a solution of 2 per cent. of tartar-emetic in the other. Haen's salt, the fluoride of antimony and sulphate of ammonium, was also used for comparison. The colours used for the subsequent dyeing process were—Brilliant green, Bismarck brown, Safranine, Methyl violet, Chrysoidine, Methylene blue, and Magenta. In general the results were unfavourable to the lactate mordant, as the shades obtained with it were usually lighter.

In cotton-printing lactic acid may find employment as a substitute for the more expensive organic acids, such as tartaric and citric acids, but not for the cheaper acetic acid. In some cases, however, its employment may be of service in the production of a specially superior result, e.g. for cochineal pink, for which the following recipe was used:—

	Grams.
Cochineal liquor of 6° Tw.	25.00
Oxalic acid	0.25
Alum.....	1.25
Starch.....	32.00
White tartar	1.25
Water.....	200.00

A swatch was printed after this recipe, and a second swatch with lactic acid substituted for the oxalic acid and acid potassium lactate for the tartar. After drying, the

swatches were steamed at 5 lb. for 30 minutes, and then soaped. The lactic print was far superior in depth and brilliancy to the oxalic colour.

As a substitute for tartaric acid for producing white discharges on Turkey red, the results were indecisive, and the same may be said of the experiments to substitute aluminium lactate for the acetate in dyeing Turkey red. Briefly summed up, the experiments described in this article would indicate that lactic acid may be used with considerable advantage in dyeing wool with alizarin, and in cotton-printing, in the place of tartaric and citric acids.

PATENTS.

Improvements in Machinery for Printing Fabrics. E. and A. Samuel, Neuville-sur-Saône, France, Eng. Pat. 3301, March 1, 1890. 8d.

This invention relates to that class of printing machinery in which the fabric to be printed is stretched upon a table, and the mechanism carrying the printing roller travels lengthwise over the fabric, which remains stationary during the printing operation. For the details of construction it is necessary that the drawings accompanying the specification should be consulted.—W. E. K.

Improvements in Doctors for Calico-Printing and other Machines. J. Thomson, Manchester. Eng. Pat. 4564, March 24, 1890. 6d.

THE object of this invention is to provide, for calico-printing machines, a doctor of any gauge or thickness, with more flexibility than has usually been the case in a plate of the same gauge. This is effected by forming perforations cut or punched out of the metal behind the working edge. The strength and weight of the metal is thus reduced, and the flexibility of the blade increased. The holes are preferably made square, but may be of any desired shape or size.—W. E. K.

Improvements in or Relating to Machines for Applying Golds, Flocks, Micas, or other Materials to Paper or other Fabrics. C. P. Huntington, Darwen. Eng. Pat. 4580, March 24, 1890. 6d.

THE gumming or sizing of the paper or other fabric is effected by means of a roller adapted to, or forming part of, a printing machine; the web is then conducted away from the drum of the machine to an additional cylinder, where it is gilded, flocked, or coated with other material by any usual process; from this cylinder the web is re-conducted to the printing machine to receive any subsequent colourings.

Synthesis of Kainite and Tachhydrite. A. de Schutter. *Compt. Rend.* **111**, 928—930.

KAINITE, one of the Stassfurt minerals, having the composition $\text{KCl} \cdot \text{MgSO}_4 \cdot 3 \text{H}_2\text{O}$, is reproduced artificially by evaporating on the water-bath molecular proportions of potassium sulphate and magnesium sulphate with a large excess of magnesium chloride. The compound separates out in monoclinic crystals of 1 mm. to 1.5 mm. in length which have the form and specific gravity of the natural mineral. The fact that the compound is not produced in the cold throws light on the mode of formation in nature.

Tachhydrite is another of the Stassfurt minerals, having the composition $\text{CaCl}_2 \cdot 2 \text{MgCl}_2 \cdot 12 \text{H}_2\text{O}$. It is formed by evaporating a solution of magnesium chloride with excess of calcium chloride on the water-bath. When sufficiently concentrated it is left to crystallise, large rhombohedral crystals being formed which possess the form and specific gravity of the natural mineral.—V. C.

Method of Preparation of Pure Phosphoric Acid.

M. Nicolas. *Compt. Rend.* **111**, 974—975.

A known quantity of pure calcium phosphate is gradually added to a slight excess of pure dilute hydrofluoric acid, contained in a leaden or platinum vessel, the mixture being well stirred after each addition. An energetic action takes place and considerable heat is evolved. When all the calcium phosphate has been added, the high temperature of the mixture must be maintained for some time in order to complete the reaction. After the removal by filtration of the calcium fluoride which is formed, the solution of phosphoric acid is evaporated. At the point when the solution commences to become viscid, the excess of hydrofluoric acid used is volatilised. The evaporation is continued until a thick syrup, containing 60—70 per cent. of phosphoric anhydride, is obtained. Meta- and pyrophosphoric acids may be prepared by further continuing the evaporation and heating.

The various calcium salts of phosphoric acid described by Erlenmeyer may be readily prepared by adding hydrofluoric acid to a large excess of calcium phosphate, and, after mixing well, dissolving out with warm water the acid salts produced. Impure phosphates, such as bone-ash, may be used for the preparation of phosphoric acid, provided that the resultant acid, after being evaporated to carbonise the organic matters present, is diluted with water, filtered and again evaporated.—E. B.

Investigations on Sets of Vitriol Chambers. S. Retter. *Zeits. f. angew. Chem.* 1891, 1—18.

THE disadvantage of working with one chamber is demonstrated by a comparatively low production of vitriol, by irregularity in the working of the plant and by the results of gas analysis. Dividing one large chamber into two smaller ones increased the production by about 40 per cent., which is in accordance with observations made by Lunge and Naef (this Journal, 1881, 633), Schertel and Sorel (this Journal, 1889, 283), on sets of three or more chambers. Gas analytical results are given for a chamber working:—(1.) Under normal conditions; (2.) with a deficiency of air; (3.) an excess of air; (4.) short of nitre; the methods adopted being those used by Lunge and Naef. Results are also given for two two-chamber-sets working under normal conditions.—H. A.

On the Tension of the Nitrous Acid of Nitrous Vitriol. G. Lunge. *Zeits. f. angew. Chem.* 1891, 37—42.

It is well known that a solution of nitrosylsulphonic acid in concentrated sulphuric acid is stable, whilst a solution of nitrous acid in weak sulphuric acid is easily decomposed, the more so the larger the quantity of water present, and the higher the temperature. Though this property of the nitrous vitriol was utilised before the introduction of Glover towers for the recovery of nitre, yet until recently the influence of varying conditions on the stability of these

solutions has not been investigated. The important rôle ascribed to the formation and decomposition of nitrous vitriol in the modern theories of the sulphuric acid process prompted Sorel to experiment on the subject with a view of obtaining more exact data regarding the decomposition of nitrous vitriol. His experiments, however, have not been carried far enough to enable him to construct tables available for practical purposes, and the importance and necessity of such tables caused the author to make further investigations, in which he was assisted by Zalciecky and Marchlewski.

The decomposition of nitrous vitriol (i.e. sulphuric acid containing nitrosylsulphonic acid and possibly free nitrous acid) depends upon four factors. (1.) Concentration of the sulphuric acid; in the following experiments this was kept between 120°—141 Tw. (2.) Temperature; the limits were between 50—90° C. (3.) Quantity of nitrous acid present; this was varied according to the strength of the acid. (4.) Quantity of gas coming in contact with the acid; this was kept constant.

The experiments were carried out in the following way. A stream of carbonic acid free from moisture and oxygen was passed through a 10-bulb-tube, containing 50 cc. nitrous vitriol; both this and the carbonic acid in the long inlet tube were brought to the desired temperature by means of a water-bath. The escaping gas passed through another tube charged with 100 cc. of concentrated sulphuric acid, to retain nitrous acid, and was finally washed with strongly acid semi-normal permanganate, which will absorb nitrogen oxide. The stream of carbonic acid was so regulated that exactly 5 litres of carbonic acid passed through the apparatus in an hour. The tube containing 100 cc. of sulphuric acid is then emptied in a 200 cc. flask, washed with pure vitriol, filled up and the mixture titrated with permanganate and checked with the nitrometer.

The nitrous vitriol was prepared by dissolving varying quantities of nitrosylsulphonic acid in pure sulphuric acid; the solution proved to be free from nitric acid.

The results are given for acids of 144°, 137°, 127°, and 120 Tw., the figures being arranged in tables showing: (1.) the absolute loss of N_2O_5 in grammes per litre of acid, after treating with 5 litres carbonic acid in one hour. (2.) The percentage loss of the nitrous anhydride present. (3.) The quantity of nitrous anhydride taken out of the nitrous vitriol by 5 litres of carbonic acid within one hour.

In placing the amount of N_2O_5 in grammes per litre on the abscissa, the loss of N_2O_5 in grammes per litre on the ordinate, and connecting the values obtained for a certain temperature, curves will be obtained which prove that in strong acids and at low temperatures the nitrous acid is in combination as nitrosylsulphonic acid, but that in diluting the liquor and raising the temperature it is converted into free nitrous acid and rapidly escapes.

The following four tables are obtained by means of the corrected curves. They can be used directly for the four acids in question. The values for acids of other strengths may be obtained by interpolation, but no great degree of accuracy need be expected.

1. NITROUS VITRIOL, Sp. Gr. 1.720

The Utilisation of By-Products of Mineral Oil Manufacture for Alkali-Making. A. Veith and C. Schestopal. *Dingl. Polyt. J.* 279, 21—22.

Tire acid and alkaline waste liquors obtained in purifying mineral oils contain sulphuric acid, caustic soda and higher hydrocarbons. It is proposed to unite these semi-liquids to obtain neutral sodium sulphate. In adding to this two-thirds of its weight of calcium carbonate and calcining, large quantities of soda are obtained. It is intended to carry out the experiments on a large scale, and so far the advantages claimed for this process are: (1) An intimate mixture of the ingredients in consequence of their semi-liquid state at atmospheric temperature; (2) the greater reducing action and heat developed by the combustion of the hydrocarbons in comparison with that by using "slack."

—H. A.

PATENTS.

Improvements in obtaining Cyanides from Residuary Liquors formed in Chemical Processes. J. S. MacArthur, Renfrew. Eng. Pat. 3071, February 21, 1889. (Second Edition.) *Ad.*

To the cyanide solutions is added an excess of a salt of iron, such as the protosulphate. After drying the precipitate, it is fused with carbonate of sodium or potassium, producing the corresponding cyanide which is then extracted by lixiviation from the insoluble residue. Or the precipitate may be fused with caustic soda or potash, a ferrocyanide being then obtained. (See also this Journal, 1890, 190.)

—S. G. R.

Improvements in and in Apparatus for the Evaporation of Brine and the Manufacture of Salt therefrom. R. C. Wilson, Birkenhead. Eng. Pat. 393, January 9, 1890. 11d.

The steam produced in the evaporation of brine in closed pans is drawn off and passed through a compressor, whereby its temperature is raised and its volume diminished. It is then delivered back again along tubes within the pans, and being condensed the latent heat evolved will evaporate more brine. The water formed by its condensation is still further utilised for heating the feed supply of brine. The pans are covered with wood and packed with a suitable

non-conducting material. The steam which is being evolved from the pan should be at a rather higher pressure than that of the atmosphere outside. If desired the steam from the first pan may be passed to a second and thence to a third. Each pan may or may not be furnished with a separate compressor driven by a common motor. The specification is furnished with three sheets of drawings.

—S. G. R.

A New Method of Treating Borates of Lime and Beracite with a View to the Manufacture of Borax and of other Borates. "The Borax Company, Limited," London. Eng. Pat. 2526, February 17, 1890. (Internat. Conv. October 2, 1889.) 6d.

THE borate of lime is washed with just enough sodium carbonate solution to decompose all the calcium sulphate present. The residue is then mixed with more sodium carbonate to decompose all the calcium borate, and the mass is diluted with water and placed in air-tight metallic receivers, steam being subsequently blown in. The temperature and pressure both rise rapidly, and the borate of calcium is decomposed with the formation of a basic soluble borate of sodium. To this is added enough boric acid to convert the basic borate into borax, which is then crystallised out.—S. G. R.

Improvements in or Appertaining to the Distillation or Treatment of Ammonium Chloride with Leblanc Alkali Waste and kindred Substances. J. L. Leith, St. Helens. Eng. Pat. 2633, February 18, 1890. 4d.

WHEN alkali waste is distilled with ammonium chloride, either an excess of the former must be used to prevent the loss of ammonia, in which case sulphur is left behind in the waste, or an excess of the chloride be taken when ammonia is lost. At the top, therefore, of the tower ammonium chloride is used in excess, whilst lower down milk of lime is added whereby the excess of chloride is decomposed and the ammonia recovered.—S. G. R.

Improvements in the Manufacture of Salt and in Apparatus and Appliances employed therein. O. E. Pohl, Liverpool. Eng. Pat. 3391, March 4, 1890. 8d.

THIS patent is a continuation and improvement of Eng. Pats. 3116 of 1872, 1503 of 1873, and 1007 of 1889 (this Journal, 1890, 189). The steam and products of combustion passing from the brine pans are led away to a drying-house, below the floor of which they pass, and which is used for drying the salt. Or this waste heat may be utilised below an ordinary brine evaporating pan, which is preferably made of galvanised iron. The petroleum furnace or gas oven is also so constructed that the products of combustion are allowed to pass directly from the furnace into the opening between the two pans which are set one above the other. The third and last portion of the patent refers to an improved means of holding in position the revolving grate at the back of the furnace. There are three sheets of drawings.—S. G. R.

Improvements in or Relating to the Manufacture of Litharge and Red Lead. G. Larrouty, St. Andre-Pez-Lille, France. Eng. Pat. 3786, March 10, 1890. 8d.

See under XIII., page 375.

VIII.—GLASS, POTTERY, AND EARTHENWARE.

Artificial Production of a Chromium Blue. J. Garnier, Compt. Rend, 111, 791.

FREMY and Verneil, in their researches on artificial rubies, attribute the blue tint which they observed *probably to chromium*. The author sent to the Academy in 1887 a sealed packet containing the formula of a blue comparable with cobalt blue, "but containing no cobalt, and producible at a low price." All the compounds having for their base chromium oxide, and melted under oxidising or indifferent conditions, being green, the blue colour observed in this case is probably due to the reducing action occurring in the experiment. It may be added that, according to the conditions of experiment, gems are obtained the tint of which is blue or violet, so it would seem that chromium may give in the dry way an entire scale of colours according to the higher or lower temperature employed and more or less reducing action.

The sealed note contained the following:—

"Process for obtaining a blue with chromium base. If there be melted together in a brasqued crucible—

	Grms.
Potassium chromate.....	1.862
Fluor spar	65
Silica	157

a fine blue will be obtained, surrounded by a pellicle of metallic chromium, which can be removed."—J. M. H. M.

Experiments on the Constitution of the Natural Silicates. F. W. Clarke and E. A. Schneider. Amer. Jour. Science, 1890, October, November and December.

OLIVINE, talc, serpentine, chlorite, mica and vermiculite, in some cases samples from several localities, were the six groups of magnesian silicates experimented on. The test experiment, after ordinary quantitative analysis, and the purification of the material, or the determination of its inclusions, was the subjection of the ground mineral to dry hydrochloric acid gas at a temperature between 383° and 412° C., i.e., between the fusing points of lead iodide and zinc. This was then compared with the effect of aqueous hydrochloric acid on the same minerals, sometimes after strong ignition. It was found that sometimes a species previously insoluble could be thus split up into a soluble and an insoluble part. The authors' conclusions are: (1) That the actions of gaseous and aqueous hydrochloric acids differ widely; (2) that in this group of minerals the gaseous acid attacks apparently only that part of the magnesium which is present as the univalent groups—Mg.OH; (3) the chlorites are not hydrated conditions of the micas, or micas plus water of crystallisation.

PATENTS.

An Improved Method of making Porcelain Tablets or Letters. E. Robson, Newcastle-on-Tyne. Eng. Pat. 352, January 8, 1890. 4d.

THE tablets or letters are moulded in clay and placed face downwards in a plaster mould. "Slip" clay is run in to form a background, and when set the background is cut into the shape required for the tablet. The whole is then replaced in the plaster mould which is filled up with clay and afterwards dried.—V. C.

Improvements in Enamelling Metals. A. E. Robinson, Wolverhampton, and W. H. Wheatley, Lewisham. Eng. Pat. 1894, February 4, 1890. 6d.

IN the ordinary process of enamelling metal the plate is first heated in a muffle, the ground enamel applied, the temperature lowered and the succeeding enamels applied. The

inventor claims to effect a better control over the temperatures, and to diminish the liability to bending of the plates by subjecting them to less handling. The plate is fixed between clamps attached to an insulating support and an electric current passed through the plate which forms the principal resistance of the circuit. The current is regulated to suit the different fusing points of the enamels employed. The electric generator is preferably of the alternating current class.—V. C.

Improvements in the Method of Frosting or Obscuring Glass Globes. W. H. Akester, London. Eng. Pat. 2293, February 12, 1890. 4d.

The improvements relate to a method of frosting glass globes such as those used with incandescent electric lamps. To obtain a white frosting, nitro-cellulose is dissolved in amyl acetate or other suitable solvent and 5 to 15 per cent. of a white powder such as kaolin is added. The emulsion is applied to the surface of the glass and the solvent evaporated off by warming to about 100° F. To obtain a coloured surface an aniline dye or other dyestuff may be added to the emulsion. This gives a comparatively clear and transparent film. A more opaque film is obtained by omitting the dyestuff and substituting a coloured earth for the kaolin.—V. C.

An Improved Process of Coating and Tinting Glass Surfaces. C. Leigh, Homerton. Eng. Pat. 3203, February 28, 1890. 4d.

Opal glass has, previously to this invention, never been tinted, unless colour applied to the surface was to be burnt in. The invention is a method of tinting applicable to opal glass equally with other glass. The surface of the glass is roughened by grinding, a coating of shellac or other gum soluble in alcohol is applied to the surface, then the dye is applied, and then the mordant. When a gum is applied in alcoholic solution the mordant can be dispensed with.—V. C.

Improvements in Machinery for the Production of Sheets direct from Molten Metal or Glass. C. M. Pielsticker, London. Eng. Pat. 6464, April 28, 1890. 8d.

See under X., page 373.

Improvements in Apparatus for Drying Clay Products and other Materials. J. P. Bayly, London. From P. Arnold, Canal Dover, I. S.A. Eng. Pat. 17,503, November 1, 1890. 8d.

The invention relates to an improved "tunnel drier," designed for drying brick and pottery materials. The drier is divided into compartments, preferably three being used, so that loading, drawing, and drying may go on systematically.

The claims made are for the combinations of flues, air ducts, and heating coils preferred by the patentee, and cannot be usefully reproduced in abstract form.—B. B.

Improvements in Gas Furnaces for Use in Glass and other Works. R. A. M. Regnault, St. Denis, France. Eng. Pat. 20,606, December 17, 1890. 6d.

See under II., page 354.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

Blast Furnace Slag and its Utilisation. R. Zsigmondy. Dingl. Polyt. J. 279, 41—43 and 69—71.

F. W. LÜRMANN asserts in *Stahl und Eisen* that E. Laugen anticipated C. Wood in the recognition of the hydraulic properties of granulated blast-furnace slag, the latter receiving his information from the former. A use was found for the new material in making building stones which were first made in Osnabrück. Slag cement was also first prepared there.

P. Gredt has compared the fusing points of slags (prepared by mixing known proportions of silica, alumina, and lime) by means of Seger's normal cones, and finds them to range from about 1,400—1,600° C. Similar experiments in which, however, lime was gradually replaced by magnesia, indicated that up to a certain point the temperature necessary to effect combination and fusion fell, but rose again on the addition of more magnesia.

Peligot has observed a similar phenomenon in the case of glass. The difference in properties between granulated and ungranulated slag has led to various attempts to explain its cause (see this Journal, 1890, 863).

Le Chatelier has put forward the following views: Granulated slag contains the whole of the energy which appears as heat if the same slag be allowed to crystallise instead of being granulated. In consequence of this its constituent molecules being endowed with more potential energy have a greater tendency to combine either among themselves or with the lime that is added to make slag cement than have those of crystallised slag. In one word the quantity of available energy in granulated is greater than that in crystallised slag.

Calorimetric experiments confirm this conclusion. Chatelier has found that the heat of solution of granulated slag is greater than that of crystallised slag; the composition of the slag used corresponded with the formula $2\text{SiO}_2, \text{Al}_2\text{O}_3, 4\text{CaO}$. Calculating the heat that would be evolved by solution of the constituent oxides of this slag in dilute hydrochloric acid (leaving out of account the heat of hydration of alumina), it is found that 1 gram. would liberate 510 cal. (small). Slowly cooled crystallised slag liberated 301 cal., while granulated slag evolved 420. It follows that the heat of formation of crystallised slag of this composition is 209 cal., while that of granulated slag is only 90 cal., whence it is obvious that each gramme of granulated slag contains an amount of energy equal to 119 cal. over and above that possessed by each gramme of crystallised slag. A practical deduction is that the quicker the cooling the better the product is suited for making slag cement. Viscous or semi-fluid slags consequently give bad cements because they have already passed to some extent into the crystalline state before granulation.

Microscopical investigation of thin sections showed that acid slags in the crystalline state were composed of long crystals placed parallel to one another; in basic slag the crystals are smaller.

Tetmajer has carried out a series of experiments to ascertain what composition a slag should have for cement making. In order to eliminate adventitious factors Tetmajer prepared slags from white marble, calcined clay and powdered quartz, having the following compositions:—

	SiO_2	Al_2O_3	CaO
1	2	0.25	2.25
2	2	0.50	2.50
3	2	1.00	3.00
4	2	0.25	3.25
5	2	0.50	3.50
6	2	1.00	4.00

Besides these two actual blast-furnace slags were used:—

	(7.) Bilbao.	(8.) Marnaval.
	Parts per Cent.	Parts per Cent.
SiO ₂	38	28
AlO ₃	10	19.5
CaO	46	45

The slags were granulated under as nearly as possible the same conditions and ground in the same ball mill. Each slag served for the preparation of three cements:—

(1.) Lime was added in the proportion demanded by the formula $m(\text{SiO}_2\text{CaO}) + n(\text{Al}_2\text{O}_3 \cdot 3\text{CaO})$. (Series A.)

(2.) Fifty parts of slaked lime were added to 100 parts of slag. (Series C.)

(3.) A quantity of lime equal to the mean of the quantities used for (1) and (2) was added. (Series B.)

The proportion of lime to 100 parts of slag in each of these is shown by the following table:—

LIME PER 100 PARTS OF SLAG.

Series.	1.	2.	3.	4.	5.	6.	7.	8.
A	14	24.5	29	0	0	17	6	12
B	32	37.2	39	25	25	33	28	31
C	50	50.0	50	50	50	50	50	50

Besides these in some cases hydraulic lime from St. Astier was used (this Journal, 1891, 258). The cements thus made were tested in compression by Le Chatelier's apparatus. The test pieces were cylinders 3×3 cm., and the cement was mixed with normal sand in the proportion of 1:3 and gauged with 11 per cent. (reckoned on the dry mixture) of water. Tetmajer did not make the test pieces in the ordinary manner (presumably with a hammer apparatus or its equivalent), but merely with a trowel used lightly. The results were compared with those given by Boulogne Portland cement similarly treated. Had the method of treatment according to the French prescription been adopted the strength of the test pieces would have been about three times as great as was the case, while the standard German process would have given even higher results.

The test pieces were left in the moulds for 24 hours and afterwards placed in cold water for periods of 7, 28, and 100 days; others were kept for 100 days in cold water and then dried for 48 hours; another set was kept in hot water for 7 days (cf. Deval's experiments, this Journal, 1891, 258), while others were exposed to moist air for 100 days.

The test pieces of all three series (A, B, and C) made from cement No. 1 fell to pieces when put into water even after being kept in air for 4 days instead of 24 hours. A comparison of the results of the cement mixtures 1 and 4, of 2, 7, and 5, and of 3, 8, and 6, showed the favourable influence of the presence of a greater percentage of lime in the slag upon the properties of the cements made therefrom. A similar result followed the increase of the percentage of alumina. Tetmajer maintains that, contrary to earlier observations, a high content of alumina does not necessarily produce a cement liable to crack. He ascribes the tendency of slag cements to crack to their containing more sulphur than Portland cement (Zsigmondy points out in a footnote that Tetmajer used raw materials free from sulphur); this is present in the slag as calcium sulphide, is oxidised by the air to sulphate, and acts in the same way as gypsum is credited with doing. Treatment of the slag with carbon dioxide is not available as a remedy, for according to Tetmajer it saturates a part of the active lime.

The use of hydraulic instead of ordinary lime for adding to the slag appears to have no particular advantage (contrast this Journal, 1890, 863). It does not even hasten the rate of setting, or at least only exceptionally. The quantity of lime added is of great importance; an addition corresponding to

the formula $\text{SiO}_2\text{CaO} + n(\text{Al}_2\text{O}_3 \cdot 3\text{CaO})$ is only desirable for poor slags. For the best slags an addition of 50 per cent. of lime is rather too high; the best proportions lie between these extremes. The richer the slag in alumina the more lime must be used; thus to Choiméde slag 40–45 per cent. is added, to Donjens slag 40 per cent., and to Cleveland slag 33 per cent. of lime.

With regard to the use of slag cement, it may be stated that it needs a considerable amount of moisture to harden it properly. Therefore if exposed after setting in ordinary building operations to sunshine or other drying agencies, it may fail not only on account of its failure to attain its full strength under these conditions, but also by reason of the cracks set up in it.

The chance of such failure is increased by smoothing the surface of the cement too much or by finishing the work with a coating of neat cement.

The quantity of water used for gauging neat slag cement should be about 25 per cent., while that requisite for a mixture of 1 part by weight of cement to 3 of normal sand is about 37 per cent. of the weight of the cement.—B. B.

PATENTS.

Waterproofing and Preserving Composition for Stone Bricks, also for Plaster and Cement Surfaces. W. Sinclair, Hull, and M. Mackay, London. Eng. Pat. 1178, January 22, 1890. 4d.

See under XIII., page 375.

New or Improved Building Material. F. Oschwald, Lenzburg, Switzerland. Eng. Pat. 17,795, November 5, 1890. (Internat. Conv. July 5, 1890.) 4d.

A substance which may be termed "peat stone" is made by mixing 2–3 parts of peat with 6–7 parts of plaster of Paris, adding water and moulding into blocks or slabs. Laths or bars of wood may be introduced to give greater stiffness; in such cases the outside of the moulded slabs should be of plaster of Paris only. The material is said to be fairly light, of good compressional strength, and a bad conductor of heat and sound.

A little cement, sand, burnt ballast, &c. may be added to the mixture, but in general peat and plaster should be the sole ingredients.—B. B.

X.—METALLURGY.

Further Contributions to the Metallurgy of Bismuth. E. Matthey. Proc. Roy. Soc. 1891, 49, 78–79.

INSTEAD of the costly and tedious wet-process previously in use for freeing bismuth from the small but detrimental trace of copper so frequently accompanying it, the author a short time ago adopted the method of fusion with bismuth sulphide (Proc. Roy. Soc. 43, 172). The disadvantage of this latter process, however, is that it necessitates a temperature sufficiently elevated to fuse the bismuth sulphide, which, unless very great care is taken, causes a loss of bismuth by volatilisation. The author has since found that this loss can be avoided if, instead of employing bismuth sulphide, a small proportion of sodium monosulphide be stirred into the fused alloy at a temperature just above the melting point of the sulphide. By this means 90 per cent. of the bismuth can be obtained entirely free from copper. The remaining 10 per cent. (skimmings), which contain the copper, being worked up again.—O. H.

The Precipitation of Gold from Chloride Solutions.
W. Langguth. Eng. and Mining J. 1891, 204.

THE Golden Reward Chlorination Works, of Deadwood, South Dakota, are now stated to work about 40 tons of ore daily. The system of barrel chlorination, in which the whole operation of chlorinating and leaching is done in the same vessel, was introduced and worked out by Mr. J. E. Rothwell. Here are chlorinated successfully refractory ores which carry from 12 dol. and upward in gold, saving from 90—97 per cent. of the assay value. There is a considerable quantity of gold solution to handle, amounting to from 8,000 to 9,000 gallons daily.

After numerous experiments with ferrous sulphate, charcoal, iron and copper sulphide, and other precipitants, it was decided that the safest, quickest, and best precipitant is hydrogen sulphide.

The mode of operation now adopted in the works is: First, to destroy the free chlorine in the gold solution, while cold, with sulphurous acid gas, which is done by drawing a stream of air over ignited sulphur with a small air pump into the precipitating tank till all or almost all free chlorine is converted into HCl. Then, turning on the hydrogen sulphide, start and finish the precipitation of the gold ($2\text{AuCl}_3 + 3\text{H}_2\text{S} = \text{Au}_2\text{S}_3 + 6\text{HCl}$). It takes less than an hour to precipitate the tank of about 5,000 gallons of gold solution. The precipitate is in a voluminous and flocculent form, that settles quickly. Usually after precipitation the tank is allowed to settle for two hours. The heaviest of the precipitate has then settled and the solution is drawn off from 1 in. above the tank bottom through a filter press, only provided with a set of heavy Canton flannel filter cloth. This process of filtration (decantation) takes usually from three to four hours—three hours when the cloth in the filter press is new, four hours when already a considerable amount of gold sulphides has been collected on the filter cloth. The precipitating tanks are placed so as to give about 25 ft. head above the presses. By cleaning up from the tank bottom into the press only once or twice a month, that is, allowing the sulphides to accumulate in the tank bottom and run down and catch in the filter press only the very small amount of gold sulphides remaining suspended in the liquid after two hours' settling, instead of filtering and gathering all the precipitated gold sulphides in the filter press after each precipitation, there is less filter cloth to burn and less loss of precipitate.

If the filter press is filled on the clearing-up day with gold sulphides, the small air-pump is connected with the filter press, and air is pumped through it for an hour to dry the mass of sulphides into hard cakes, which are easily handled and removed. The precipitate thus obtained is roasted in a muffle furnace, mixed with a little borax and nitre, and smelted down to bullion. If carefully handled there is little loss. The bullion is always about 900 to 950 fine in gold, the balance being some silver, copper, lead, and arsenic.

The advantages derived from this method of precipitation are evident from the facts given above, and are enumerated as follows:—

1. There is no gold left or remaining undetected in solution after the precipitation with sulphuretted hydrogen has been completed.
2. The free chlorine is cheaply, quickly, and easily transformed into hydrochloric acid. The latter, with the sulphurous gas converted into sulphuric acid, assists the precipitation of gold with sulphuretted hydrogen, in so far as gold is more quickly and better precipitated out of an acid solution than out of a neutral or alkali one. There is no heating of solution, no lead lining affected, and no time wasted to decompose free chlorine.
3. There are required only crude chemicals and a simple apparatus.

4. The precipitate is in a flocculent form, and settles quickly. There is little loss if carefully handled.

If copper be present, the gold is precipitated from a nitric acid solution by sulphuretted hydrogen.

Refining Silver Bullion. F. Gutzkow. Eng. and Mining J. 1891, 237.

A NUMBER of years ago the author devised a method for refining silver bullion by sulphuric acid, in which iron was substituted for copper as precipitant of silver, the principal feature being the separation of pure crystals of silver sulphate. A full description of this process may be found in Percy's Metallurgy, "Silver and Gold," page 479. The process has been extensively worked in San Francisco and in Germany in refining bullion to the amount of more than a hundred million dollars' worth of silver. Its more general application has been hampered, however, by the circumstance that the patent had been secured by one firm which limited itself to its utilisation in its California works. The patent having expired, the author lately introduced a modification of the process by which the apparatus and manipulations are greatly cheapened and simplified. In the following account is given a short description of the process in its present shape.

Preparing the Silver Sulphate.—The bullion, containing, essentially, silver, copper and gold, is dissolved by boiling with sulphuric acid in cast-iron pots. The difference between the new process and the usual practice consists in the use of a much larger quantity of acid. Thus, in refining ordinary silver "doré" four parts of acid are used to one part of bullion. Of this acid one part is chemically and mechanically consumed in the dissolving process, and the remaining three parts are fully recovered and at once ready for re-utilisation, as will be described hereafter. In the usual process—understanding thereby, here and in the following, the process practised at the United States mints, for instance—two parts of acid are employed for one of bullion; all of this is lost, partly through the dissolving and partly in being afterwards mixed with water, previous to the precipitation of the silver by copper. Economy in acid being, therefore, imperative, the silver solution finally

becomes much concentrated, and it requires high heat and careful management to finish the solution of the bullion. Bars containing more than about 10 per cent. of copper cannot be dissolved at all, owing to the separation of copper sulphate insoluble in the small amount of free acid finally remaining. The advantage gained by dissolving bullion with abundance of free acid in the improved process is so evident that it merely requires to be pointed out. For bullion containing 20 per cent. of copper the author employs six parts of acid to one of bullion; for base metal still more acid, and so on, never losing more than the stoichiometrical percentage of acid and recovering the remainder.

In this description he, however, confines himself to the treatment of ordinary silver ore with less than 10 per cent. of copper.

In the diagram A A represent two refining pots, 4 ft. in diameter and 3 ft. in depth, each capable of dissolving at one operation as much as 400 pounds of bullion. The acid is stored in the cast-iron reservoir B, which is placed on a level sufficiently high to charge into A by gravitation, and is composed of fresh concentrated acid mixed with the somewhat dilute acid regained from a previous operation. After the bullion is fully dissolved all the acid still available is run from B into A A. The temperature and strength are thereby reduced, the fuming ceases, any still undissolved copper sulphate dissolves, and the gold settles. In assuming that the settling of the gold takes place in A itself, the author follows the practice of the United States mints. In private refineries, where refining is carried on continuously, the settling may take place in an intermediate vessel, and A A be at once recharged. Owing to the large amount of free acid present, the temperature must fall considerably before the separation of silver sulphate commences, and sufficient time may be allowed for settling if the intermediate vessel be judiciously arranged.

Separating the Silver Sulphate.—The clarified solution is siphoned off the gold from A A into C, which is an open cast-iron pan, say 8 ft. by 4 ft., and 1 ft. deep. It is supported by means of a flange in another larger pan—not shown in the diagram—into which water may be admitted for cooling. Steam is blown into the acid solution, still very hot, as soon as C is filled. The steam is introduced about 1 in. below the surface of the liquid, blowing perpendicularly downward from a nozzle made of lead pipe through an aperture $\frac{1}{2}$ in. in diameter. Under these circumstances the absorption of the steam is nearly perfect, and takes place without any splashing. The temperature rises with the increasing dilution, and may be regulated by the less experienced by manipulating the cooling tank. An actual boiling is not desired, because it protracts unnecessarily the operation by the less perfect condensation of the steam. No separation of silver sulphate occurs during this operation (and, consequently, there is no clotting of the steam nozzle), the large amount of free acid, combined with the increase of temperature, compensating for the diminution of the solubility of the sulphate by the dilution. The most important point in this procedure is to know when to stop the admission of steam. To determine this, the operator takes a drop or two of the solution upon a cold iron plate by means of a glass rod and observes whether after cooling the sample congeals partly or wholly, into a white mass of silver bisulphate, or whether the silver separates as a monosulphate in detached yellow crystals, leaving a mother-liquor behind. As soon as the latter point has been reached, steam is shut off and the solution is allowed to crystallise, cold water being admitted into the outer pan. The operator may now be certain that the liquid will no longer congeal into a soft mass of silver bisulphate, which on contact with water will disintegrate into powder, obstinately retaining a large amount of free acid; but the silver will separate as a monosulphate in hard and large yellow crystals retaining no acid and preserving their physical characteristics when thrown into water. After cooling to, say, 80° F., the silver sulphate will have coated the pan C about 1 in. thick. There will also be found a deposit of copper sulphate when the mother-acid, after having been used over and over again, has been sufficiently saturated therewith. Lead sulphate separates in a cloud, which, however, will hardly settle at this stage.

The whole operation just described, which constitutes the most essential feature of the author's improvement upon his old process described in Dr. Percy's work, is a short one, as the acid requires by no means great dilution. The steam has merely to furnish enough water to dilute the free acid present to, say, 62° B. Areometrical determination is, of course, not possible on account of the dissolved sulphates.

Reducing the Silver Sulphate to Fine Silver.—The mother-acid is pumped from C to the reservoir B, for this purpose an iron pipe connecting the top of B with a recess in the bottom of C. The tank B is cast as a closed vessel,

with a manhole in the top, which is ordinarily kept closed by an iron plate resting on a rubber packing. The air is exhausted from B by a steam injector, and the acid rises from C and enters B without coming in contact with any valves. The volume of fresh commercial acid necessary for another dissolving operation, say 800 pounds, more or less for refining 800 pounds of bullion in A A, is lifted from some other receptacle into B in the same manner. The mixture of the two acids in B now represents the volume of acid to be employed for dissolving and settling the next charge of 800 pounds of bullion in A A. In this reservoir, B, the cloud of lead sulphate mentioned above finds an opportunity for settling.

The crystals of silver sulphate are detached from C by an iron shovel and thrown into D. D is a lead-lined tank about 4 ft. by 4 ft. and 3 ft. deep. It is divided into two compartments by means of a horizontal, perforated false bottom made of wood. From the lower compartment a lead pipe discharges into the lead-lined reservoir E. Warm distilled water is allowed to percolate the crystals until the usual ammonia test indicates that the copper sulphate has been sufficiently dissolved. Then the outflow is closed, sheets of iron are thrown on and into the crystals, the apparatus is filled with hot distilled water, and steam is moderately admitted into the lower compartment. Ferrous sulphate is formed, and in connexion with the iron rapidly reduces the silver sulphate to the metallic state, the reduced silver retaining the heavy compact character of the crystals. When the reaction is completed, as indicated by the chlorine test, the liquid is discharged into E, the iron sheets are removed and the silver is sweetened either in the same vessel, D, or in a special filtering vessel which rests on wheels and may be run directly to the hydraulic press.

The vat, E, is the great reservoir where all liquids holding silver sulphate in solution are collected; for instance, that from sweetening the gold and from washing the tools. Sheets of iron here precipitate all silver and copper, and the resulting solution of ferrous sulphate is, with the usual precautions, discharged into the sewer. Occasionally when copper and silver have accumulated in E in sufficient amount the mass is thrown into D, silver sulphate crystals are added and sheet copper is thrown in, instead of sheet iron. There results a hot, neutral, concentrated solution of copper sulphate which may be run at once into a crystallising vat for the separation of commercial crystals of copper sulphate. It will be readily understood, of course, that if there should be any advantage in manufacturing that commercial article, besides the amount prepared as described, which represents merely the copper contained in the bullion, copper sheets may be regularly employed for reducing the silver sulphate in D. The author trusts that the practical refiner will recognise that the manufacture of commercial copper sulphate is thus effected in a more rational and economical manner than by the present method of evaporating from 25 B. to 35 B, and of saturating by oxidised copper, generally in a very incomplete manner, the large amount of free acid left from the refining by the usual process. However, the sale of copper sulphate is but rarely so profitable that a refinery should not gladly dispense with that troublesome and bulky manufacture, especially the government establishments, which, besides waste much valuable space with the crystallising vats.

The great saving in sulphuric acid, amounting to about 50 per cent. of the present consumption, has already been pointed out. Another advantage the author merely mentions, namely, the easier condensation of the sulphurous fumes in refineries situated in cities, because the larger amount of acid available for dissolving, greatly facilitates working and makes the usual frequent admission of air into the refining pot for the purpose of stirring and testing unnecessary.

The more air is excluded from the refining fumes the easier they can be condensed.

Work may be carried on continuously, the vessels C and D being empty by the time a new solution is finished in A A. Thus, the plant shown in the diagram, covering 26 ft. by 16 ft., allows the refining of 40,000 ounces of fine silver in 24 hours; that is, four charges in A A of 800 pounds each.

The Nickel and Copper Deposits of Sudbury, Canada.

Robert Bell. Bull. Geolog. Soc. Amer. February 1891; Eng. and Mining J. 1891, 328.

THE nickel and copper district of Sudbury, Ontario, is situated in the course of the best known and perhaps the longest Huronian belt in Canada. Beginning in the west, the general northerly boundary of this great belt commences at the promontory of Nainaiuse on the east side of Lake Superior, and runs approximately parallel to the shore of that lake, the St. Mary's River and the north shore of Lake Huron as far as Spanish River, leaving a border of Huronian rocks of varying width between the water and the Laurentian nucleus to the north. Near Spanish River the dividing line between the two systems turns inland and runs north-easterly nearly to Lake Wahnapiata, whence it trends northward and north-westward till it gains a point lying north-east of Michipicoten on Lake Superior, thus almost surrounding a large elliptical area of Laurentian rocks.

The stratified Huronian rocks and also the gneiss and quartz-syenite of the Sudbury district are traversed by dykes of grey, coarsely crystalline diabase, which are often large and can be traced for considerable distances. Their commonest course is about west-north-west. They all have the same physical characters and appear to be of identical composition. The sound, fresh rock is extremely tough, but the exposed surfaces disintegrate easily under the weather into brown, crumbling debris, especially along the joint-planes and at their angles. The outer portions of the masses, thus separated, scale off concentrically, so that they become rounded and boulder-like. These dykes apparently play an important part in the economic geology of the district.

Referring to the nickel and copper ores for which this district is becoming famous, there is much uniformity, both as to characters and the conditions under which they occur. These deposits are not confined to the undoubted Huronian rocks, but are equally abundant within the gneiss and quartz-syenite areas, and may be said to be connected with a certain geographical area rather than with a single geological horizon. The ore consists in all cases of a mixture of chalcopyrite and nickeliferous pyrrhotite. The area over which it has been found up to the present time extends from the Wallace mine, on Lake Huron, in the vicinity of La Cloche, north-eastward to the north side of Lake Wahnapiata, a distance of about 70 miles, and from the south-eastern boundary of the Huronian belt, in the Sudbury district, north-westward to the limits of the Geneva Lake outlier, a distance of about 50 miles.

The investigations of the writer in this district have shown that the combined nickel and copper ore is found on or near certain lines of contact between diorite, and gneiss or quartz-syenite, but only at certain points on these lines, the concentration of the ore at one place more than another being probably caused by the intersection of the ore-bearing belts either by one of the diabase dykes above described or else from the pinching-in or perhaps from a transverse disturbance of the belt. The ore seems to have been derived in all cases from the diorite, but for some reason the proximity of the gneiss or quartz-syenite appears to be also favourable for the production of large deposits.

The dioritic wall rocks on either side and also the included boulders and even the smaller fragments are often thickly impregnated with disseminated grains and patches of all sizes, both of pyrrhotite and chalcopyrite. These spots of ore have usually rounded outlines in cross-section and approach spherical and ovate forms. The two sulphides may occur side by side in the same isolated kernels; but just as frequently the latter consist of one or the other alone, although in such cases the same rock section may contain as many of the one kind as the other, and all indiscriminately mingled together.

Numerous analyses of the ores have shown that the nickel is confined to the pyrrhotite, in which it is present in the proportion of about 1 per cent. to 5 per cent.

PATENT.

Improvements in Machinery for the Production of Sheets direct from Molten Metal or Glass. C. M. Pielsticker, London. Eng. Pat. 6164, April 28, 1890. 8d.

THE present practice in making metal sheets is to cast ingots or slabs and then reduce these by repeated rollings and reheating. Attempts have been previously made to produce sheets directly from molten metal by pouring the metal: (1) between two revolving rollers; or (2) between a revolving wheel and the surface of an enclosing fixed semi-circular segment. By these means none but very thin plates could be satisfactorily produced. In this invention the machinery consists of a large receiving roller of 5 ft. diameter more or less, and of a length equal to that of the plate to be produced. With this are combined small forming rollers arranged in succession part way round the periphery of the large roller, and revolving at the same rate as the large roller. The rollers can be cooled by a current of water circulating through them. The molten metal flows on to the surface of the large roller and is prevented from escaping sideways by flanges with which the large roller is provided. These flanges embrace the small rollers and are of a depth greater than that of the thickest plate which it is proposed to roll. The distance between the large roller and the small rollers can be adjusted according to the desired thickness of the plate. When dealing with metals of high melting point, such as steel, the first small roller is made of refractory material and is heated from inside by the flame of a blow-pipe. The rollers are coated with plumbago or other material to prevent adhesion to the molten metal. In the case of metals of high melting point the machine is fed direct from a furnace divided into two compartments by a wall or bridge in which is a stopper which can be operated so as to regulate the flow of metal. When applied to forming sheets of glass, the rollers should be warmed by a blow-pipe flame as above described, and the sheet of glass stretched and annealed as it leaves the last roller.—V. C.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

Edison's Electricity Meter. Electr. Rev. 28, 118.

THE amount of electrolytic gas evolved from acidulated water is measured by means of a suitable form of gas meter. The acidulated water is contained in a closed vessel, the level being kept constant by a syphon tube from a reservoir which is kept full by the action of a trap.—V. C.

The Chemistry of Secondary Cells. Ayrton, Lamb, Smith, and Robertson. Journ. Inst. Electrical Engineers, 19, 659—747.

THE investigation carried out by the above authors included chemical analyses of plugs taken from the positive and negative plates of E.P.S. cells of the 1888 type at all stages of charge and discharge. The potential differences were also measured, as well as the resistance of the cell itself and of the lugs.

The results of the chemical examination are as follows. At end of charge and at beginning of discharge the composition of the positive plugs were practically the same as that of pure PbO_2 . On the negative plugs the sulphate decreased during the process of charging until at the end of the charging there was practically nothing but pure lead. With the removal of the last traces of sulphate there was a rapid rise in potential difference. During discharge the amount of sulphate increased, and towards the end of discharge there was decided evidence of peroxide on the negative plates. On the positive plate

the particles of peroxide very soon get coated during discharge with a layer of lead sulphate, which protects the peroxide from further action. A large proportion of active material still remains at the end of the discharge. The loose powdery surface of the positive plate seems to become completely converted to lead sulphate. When the peroxide in the surface of the plate falls to about 31 per cent. the cell loses its E.M.F. very rapidly, owing to the inactive layer of sulphate impeding the action of the sulphuric acid on the active material behind it, and also to the formation of peroxide on the negatives. The diffusivity of the acid is decreasing, and it has to penetrate further into the plate to find active material. When the whole of the paste approaches this composition of 31 per cent. of peroxide, the cell loses its E.M.F. entirely.

On the whole the rate of chemical action at the top of the plates is greater than at the bottom; this distribution apparently depending on difference of current density.

With regard to the formation of PbO_2 on the negative plate, Gladstone and Tribe have already pointed out that once it is formed more rapidly than it is reduced, the two plates must rapidly approach electrical equilibrium; that when the circuit is broken local action can alone take place, and this will reduce the peroxide on the negative plate. On making the circuit again the cell gives a current; and in this way Gladstone and Tribe account for the rescuitating power of the cell, as well as for the rise of E.M.F. on breaking the discharged circuit.

With regard to the resistance of the cells it was found that about one-seventh of the whole mean resistance of these accumulators is that of the lead lugs. Further, that if the contacts between the lugs of successive cells be allowed to become dirty by acid spray falling on them, the resistance of the accumulator when joined up in series may be increased by as much as 25 per cent. Hence it is well that accumulators which are to remain joined up for a long period should have the adjacent lugs fused together; and further, it is recommended that the lugs should be made of greater cross-section than is generally the case.

Construction and "Forming" of E.P.S. Plates.—The positive plates contain about 48 per cent. more peroxide than is required to be converted to sulphate in the discharge. This appears to be necessary (1) because, if completely "formed," the positive plate would be liable to fall to pieces; and (2) on account of the coating of the peroxide with sulphate, which prevents part of the peroxide from entering into the chemical reaction.

With regard to the process of "forming" Ayrton gave the following method as that of the E.P.S. Company. Mr. King, of the E.P.S. Company, does not acknowledge the accuracy of the data.

Positive Plates, $8\frac{1}{2}$ in. by $7\frac{1}{2}$ in. by $\frac{1}{4}$ in. Two ampères per plate, or .028 ampère per sq. in. sent for 18 hours.

Negative Plates, 9 in. by $9\frac{3}{4}$ in. by $\frac{3}{16}$ in. One-and-a-half to two ampères per plate, i.e., .017 to .023 ampères per sq. in. for 120 hours.

Efficiency of E.P.S. Accumulators was dealt with also in a previous paper by the same authors (read at July meeting of the Institution). It was found that if charged with 9 ampères and discharged with 10 a number of times without intermission between 1.8 and 2.4 volts per cell, till a "steady state" is reached, the quantity efficiency is about 97 per cent., and the energy efficiency 87. In the course of the discussion Sir David Salomons advocated as ultimately economical the practice of using a larger battery for given work than would be indicated by the maker's statements. In this way the efficiency may be increased, e.g., from 70 per cent. to 80 or 85 per cent., and hence a greater economy in daily working, which more than outweighs the difference in first cost. This principle, however, as was pointed out by Mr. Frazer, cannot be applied to the case of electric traction, since the weight of the accumulator has to be considered.

From their investigation of the relation between resistance and distance apart of the plates the authors conclude that the resistance of an accumulator takes the form—

$$p + ld$$

where p is a constant for a particular cell depending on resistance of the plates themselves, &c., l is a constant depending on the area of the plates, the temperature, and density of the liquid, &c., and d is the distance between the plates.—V. C.

Dry Elements. Elektrotech. Zeits. 11, 31.

A SERIES of experiments on the comparative merits of six different dry elements was conducted in the physical laboratory of the Munich University during 1889—90. The elements examined were those of Hellesen, Bender, Thor, Gassner, Jenisch, and Wolfesmidt. The following points were investigated:—(1.) Change of E.M.F. on open circuit. (2.) Variation of E.M.F. with temperature. (3.) Determination of internal resistance. (4.) Fall of E.M.F. on closed circuit and recovery on open circuit. As the result of these trials it was found that the Hellesen's and Bender's elements were the best. Of these two Hellesen's has less polarisation and smaller internal resistance. After long working, however, Bender's recovers better. Thor's and Gassner's stand to each other in a similar relationship. Jenisch's and Wolfesmidt's elements are only suitable for use in cases where the circuit is only closed for a short time. This investigation possesses considerable interest since a good dry battery is a desideratum for telegraphic and telephonic work, as well as for houses fitted with electric bells.—V. C.

Preservation of Accumulators. G. Roux. Electr. Eng. 7, 181.

EXPERIMENTS to determine the conditions under which accumulators best preserve their charges when left unworked. The liquid was covered with paraffin wax with a small hole to allow the gas generated in charging to escape. The cells are of glass and are charged on oil insulators. It is important to charge to saturation. Two Julien accumulators treated in the above manner only lost 6 per cent. of their charges when left to themselves for $2\frac{1}{2}$ months.—V. C.

Influence of Hardening Steel upon its Electrical Resistance. H. Le Chatelier. Compt. Rend. 112, 40—43.

THE process of hardening steel modifies both its chemical condition and ultimate structure, and the alteration caused by each of these two orders of phenomena must be carefully distinguished from that produced by the other. Osmond has already studied this question and has taken advantage of the alterations of the properties of the carbon in steel to characterise the chemical condition of the metal. Chatelier has now adopted the measurement of its electrical resistance as a method of greater precision for the same end. His experiments were carried out on wires 100 mm. long and 2 mm. in diameter. The following table shows the electrical resistance and content of carbon of the specimens used:—

	I.	II.	III.	IV.
Resistance calculated for a wire 1,000 mm. \times 1 mm.	0.19	0.25	0.27	0.22
Carbon, per cent.*	0.085	0.485	0.67	0.83

* ω (= ohm) in original.

On hardening the steel at different temperatures it was found that a change of state indicated by a sudden increase in electrical resistance occurred at a point identical with that at which the transformation of carbon takes place, viz., at 730° C., thus confirming one of Osmond's main conclusions.

On annealing the steel the resistance falls again in a manner corresponding to the change observed in other physical properties of the metal. The author considers the method likely to be useful in further research.—B. B.

PATENTS.

Improvements in Secondary Batteries and Plates or Elements therefor. W. P. Thompson, London. From "The Gilson Electric Company of Europe," Paris, France. Eng. Pat. 2091, February 8, 1890. 8d.

THE plates are in the shape of lead trays with a slight rim, and are placed horizontally in the cells. The bottoms of the trays are perforated obliquely with numerous small holes. The active material covers the tray and fills the perforations.—E. T.

Improvements in Secondary Batteries. E. T. Mackrill, Aylesbury. Eng. Pat. 2845, February 21, 1890. 4d.

SMALL balls or pellets of wax, or other substance unaffected by the acid of the cells, are floated upon the surface of the electrolyte in order to prevent spraying as the bubbles rise to the surface during overcharging.—E. T.

Improvements in and relating to and in the Manufacture of Electric Secondary Cells. A. M. F. Laurent-Cely, Paris, France, and J. A. Timmis, London. Eng. Pat. 2945, February 24, 1890. 11d.

CHLORIDE of lead is melted in a closed furnace, and a certain proportion of pure zinc added. Pastilles of any desired shape are cast of this mixture in suitable moulds. These pastilles are then purified from any oxide—the presence of which, the inventors claim, is almost entirely prevented by this method of working—by treatment with hydrochloric acid, and are then washed with water. To oxidise the pellets they are placed on plates of zinc in water slightly acidulated with hydrochloric acid; an electrolytic action is set up which reduces them to porous lead, and they are then oxidised by exposure to the air at temperatures rising to 300° C. Finally a grid is cast round the pastilles and the plate is ready for electrolytic formation to produce peroxide of lead.

For the other plates, the pastilles of chloride have their grid cast round them *before* reduction. The whole plate is then coupled to zinc plates in acidulated water until the pastilles are reduced to spongy lead.

The active material produced in this way is said to be much less dense, and therefore more porous, than that produced by ordinary processes; to have a larger storage capacity weight for weight, and greater rates of charge and discharge.

The plant required for the above operations is described and illustrated on seven sheets of drawings.—E. T.

Improvements in or connected with the Manufacture of Secondary Battery Elements. J. S. Stevenson, South Shields. Eng. Pat. 3967, March 13, 1890. 6d.

By a previous patent (11,390 of 1887; this Journal, 1888, 572) the inventor forms plates by pouring melted lead round pellets of active material in a suitable mould. In the present specification methods of producing these pellets are described. A layer of active material is spread over the face of a die and by hydraulic pressure is formed into a cake with grooves running along and across it. The cake when dry can be broken at these grooves into small pellets as desired.—E. T.

Improvements in Electric Batteries and Lighters for Cigars and other Purposes. D. Robertson, Glasgow. Eng. Pat. 18,412, November 15, 1890. 6d.

THE improvements are to prevent spilling of the liquid, to enable the cell easily to be taken to pieces to be recharged, and to give an ornamental appearance to the whole. The battery cell is in a metal case; the current is produced by pressing a knob and thereby immersing the zinc in the electrolyte; on releasing the knob the zinc is removed from the liquid by a spring.—E. T.

Improvements in Electrical Storage Batteries or Accumulators. H. H. Lake, London. From G. E. Hatch, Cambridge, U.S.A. Eng. Pat. 19,155, November 25, 1890. 6d.

THE active material is lodged in grooves or indentations on each side of porous plates—peroxide on one side, spongy lead on the other. Thin lead is placed between the various porous plates to make contact with the active material in the latter, and the whole bound together. The electrolyte fills the pores of the porous plates.—E. T.

XII.—FATS, OILS, AND SOAP MANUFACTURE.

Mineral Lubricating Oils used in Italy. V. Villavecchia and G. Fabris. Report of the Central Laboratory of the Italian Customs Department, 1891.

See under XXIII., page 390.

XIII.—PAINTS, PIGMENTS, VARNISHES, AND RESINS.

PATENTS.

A Composition suitable for Lining Casks and like Vessels and for Making Screw Stoppers for Bottles. W. Sinclair, Hull, and M. Mackay, London. Eng. Pat. 1177, January 22, 1890. 4d.

THE invention is intended for vessels and stoppers used for beers and ales, the compound not affecting or being affected by acids or other chemicals contained in those liquors. The ingredients are as follows, the powdered pipe-clay being omitted if the composition is not to be used for moulding stoppers:—Shellac, 4½ lb.; rosin, 1½ lb.; wood carbon, 4 lb.; powdered clay, 4 lb.; palm wax, ½ lb. These ingredients are agitated with 1½ gals. of methylated spirit, which "amalgamates all of them into a compound." Without the clay the compound is semi-liquid, and can be run or brushed over the surface to be coated, and allowed to dry.—A. G. B.

Waterproofing and Preserving Composition for Stone, Bricks, also for Plaster and Cement Surfaces. W. Sinclair, Hull, and M. Mackay, London. Eng. Pat. 1178, January 22, 1890. 4d.

ONE lb. of gum "dammer" is dissolved in 1 gal. of hot turpentine or hot mineral spirit, and 2 lb. of paraffin wax added. The paraffin dissolves, and the composition when cold can be brushed on to the surface to be waterproofed. Dirty surfaces should be first cleansed. The compound is kept in jars carefully corked.—A. G. B.

Improvements in or relating to the Manufacture of Litharge and Red Lead. G. Larrony, St. Andre-Pez-Lille, France. Eng. Pat. 3786, March 10, 1890. 8d.

IN the present method of making red lead, the metal has first to be converted into litharge, which is then washed to free it from particles of unoxidised lead, and finally heated in boxes for 72 hours at a temperature not above 320°; if the litharge is not completely converted into red lead by the end of this time it is replaced in the furnace and heated for 144 hours.

By this invention the lead or litharge is converted directly into red lead. The finely powdered lead or litharge is put on iron trays contained in an iron case; the case is jacketed and surrounded by superheated steam. The whole is situated in the flue of the furnace which superheats the steam, so that the smoke and gases from the grate may surround the jacket and serve to keep up its temperature.

The following advantages are claimed—(1) the regular and certain manufacture of red lead by means of superheated steam, the temperature 300°—320° being obtainable with precision and easily maintained; (2) considerable economy of fuel, as the steam requires only very little coal to superheat it, and in this condition gives up very easily the heat it contains; (3) saving of time, litharge and red lead being manufactured by this process in at most a quarter of the time required by the methods hitherto known. Plans of the furnace accompany the specification.—A. G. B.

An Improved Furniture Polish. A. McMillan, Thoruliebank. Eng. Pat. 4321, March 19, 1890. 4d.

THE following ingredients are mixed together in or about the proportions given:—Linseed oil, 1 gal.; butter of antimony, from $\frac{1}{4}$ to 1 pint, as desired; spirits of wine, $\frac{1}{2}$ pint; white vinegar, 1 quart; "gum cassia, a few ounces."

—A. G. B.

XIV.—TANNING, LEATHER, GLUE, AND SIZE.

PATENT.

An Improved Leather Finishing Machine. W. W. Horn, London. From G. W. Lennox, Ilavenhill, U.S.A. Eng. Pat. 15,286, September 26, 1890. 3d.

LEATHER, after having been blacked, has to be treated with a "seasoning solution" consisting of "red aniline dye, blood albumen, extract of logwood, milk, and water" to "set" the black colour, and enable the leather to be polished afterwards. The "seasoning solution" has to be well rubbed in, and hitherto this has been done by hand.

In the machine patented the leather is stretched on a table capable of universal motion, and pressed against a padded roller fed with the solution with which it is to be treated; the solution is contained in an overhead reservoir, and is kept agitated by a set of rotating blades. In order to enhance the ease with which the table is moved so as to present every portion of the area of the leather to the action of the roller, the grip of the latter on the leather tending to oppose displacement of the plate is neutralised by suitable counterweights. Splashes and a drip trough shield the leather from any surplus solution that might fall upon it.

—B. B.

XV.—MANURES, Etc.

The Noxious Vapours of Manure Works. J. Morrison.

See pages 338—340.

Agricultural Value of Ammonium Salts. P. Wagner. J. f. Gasbelenchtung, 33, 660—662.

THE author being commissioned to investigate the efficiency of nitrogen in ammonium sulphate and in Chili saltpetre on different soils and also to inquire to what extent, in what direction and upon what soils the efficiency of ammonium

sulphate as a manure can be raised by simultaneous applications of lime or marl or "Thomas" slag, instituted numerous field and pot experiments. The former, under the control of Märcker, have indicated that the action of ammonium sulphate on barley, oats, and sugar beet can be augmented by simultaneous calcareous manurings, a point confirmed by the author's experiments, especially as regards soils deficient in lime. In such cases, even when lime, either alone or when used with nitrate, has little or no action; its beneficial effect with ammonium salts is, nevertheless, manifest. Märcker's experiments also show that, on an average, ammoniacal nitrogen is less active than nitric nitrogen, this being more marked with barley, potatoes, and sugar beet. The author has also confirmed this view for certain soils, and, attributing the inactivity of ammoniacal nitrogen to the lack of fixed bases in ammoniacal manures, asserts rightly that the soil should contain lime and also potash, or potash and soda, in sufficient quantity, if ammonium salts are to work efficiently, therefore he recommends the use of lime, Stassfurt salts—in fact, mineral along with the ammoniacal manures. The sulphuric acid in the ammonium salts is not regarded as the injurious agent.

—D. A. L.

PATENT.

Improvements in Fertilising Compounds or Fertilisers. J. Patterson, Philadelphia, U.S.A. Eng. Pat. 16,793, October 21, 1890. 6d.

TWELVE hundred pounds of unslaked lime, 1,200 lb. of powdered gypsum, 3,150 lb. of powdered "rotten rock," 4,000 lb. of "muck or common bog deposit," 300 lb. of sulphate of iron, and 150 lb. of salt, are mixed, the last two ingredients being previously dissolved in water. More water is then added, in sufficient quantity to slake the lime, and the mixture allowed to remain under cover from 3—6 months. (By "rotten rock" is meant "rock which is decomposed or partially decomposed.") The proportions may be varied. The substance thus prepared is said to be a valuable fertiliser.—B. B.

XVI.—SUGAR, STARCH, GUM, Etc.

Further Experiments on the Introduction of Home-Grown Sugar. G. Schack-Sommer.

See pages 318—326.

Gummy Exudation from Beetroots. E. O. v. Lippmann. Ber. 23, 3564—3566.

THE author observed a gummy exudation from some of the larger but unripe roots—used as test samples—which had been stored, wrapped in paper, in a room. The substance, which could be easily detached from the roots, formed brittle, faintly yellow, transparent drops, possessing neither taste nor smell, and resembled ordinary gum. It was insoluble in cold water and in alcohol, and evolved on burning the odour characteristic of carbohydrates, leaving only a trace of ash, which consisted principally of lime. Alkalis slowly dissolved it on heating, but from the neutralised solution it was reprecipitated by alcohol in a form which dissolved by digestion with water, to a neutral solution having a dextro-rotation. The amount of the latter was not ascertained, as the solution was not clear, and the quantity of material was insufficient for further determinations. The crude substance gave numbers on analysis agreeing, when corrected for ash, with the empirical formula $C_{11}H_{20}O_{10}$. It also yielded furfuraldehyde, corresponding to 8.84 per cent. of furfuranide, on distillation with sulphuric acid, and mucic acid 41.83 per cent. on oxidation with nitric acid.

By prolonged heating on the water-bath with dilute sulphuric acid, the compound was hydrolysed, arabinose and galactose, both of which were isolated and identified, being apparently the sole products. It would, therefore, seem to be a mixed anhydride of these two sugars, a view in harmony both with the above formula and also with the amounts of furfuranide and nucleic acid which the compound yields, although as a gum, its molecule is probably more complex. These statements can only be regarded as provisional, as sufficient material was not available to even establish the individuality of the substance. The author has not succeeded in separating the substance from beetroots subsequently experimented with, either by allowing them simply to remain aside as before, or by puncturing the tissues; it therefore seems to be a chance product.—A. R. L.

On the Influence of Some Inorganic Salts on the Specific Rotatory Power of Cane Sugar. K. Farnsteiner. Ber. 23, 3570—3578.

THREE series of experiments were made. In the first, the weights of sugar and water were constant, whilst that of the salt was varied; in the second, the weights of the salt and water were constant, whilst that of the sugar was varied; and in the third, the weights of the sugar and salt were constant, whilst that of the water was varied.

In preparing the solution, the amount of salt used was dependent on its properties. All the bodies were weighed, except in the case of hygroscopic salts, in which cases the solution was analysed. The observations of the optical activity were made with a half-shadow instrument with a quartz-wedge compensation and a Ventzke sugar scale (one scale division with a gas flame = 0.3165 of a degree, according to Landolt, Sitzungsber. der Akad. d. Wissensch. zu Berlin, 1887, 48). The determinations of the density and optical activity were made at 17.5° C., the density being calculated taking water at 4° C. as unity.

	8.817	1.1108	65.44
	18.677	1.0917	65.30

It may be noted that in general the greater the amount of salt present, the greater is the specific rotatory powers lowered, and that other things being equal the lowering is greater the less the molecular weight of the salt is, that is, the depression is inversely proportional to the molecular weight.—A. L. S.

The Reduction of Fruit-Sugar (Levulose). E. Fischer. Ber. 23, 3684--3687.

On the reduction of fruit-sugar to a hexahydric alcohol, the carbon atom of the carbonyl group becomes asymmetric. From this it might be expected that two stereo-isomeric alcohols should be formed under these conditions, which would combine to form a third body.

This is the case with some ketones, as for example, in the conversion of pyrotartaric acid into inactive lactic acid.

Up to the present only mannitol has been obtained by the reduction of fruit-sugar, and it appears as if the analogy did not hold in this case; this however, is not borne out by the fact that mannonic and the stereo-isomeric gluconic acids are produced by the action of hydrocyanic acid on arabinose, a fact which previously led Fischer to conclude that these acids and the corresponding sugars and alcohols contained one asymmetric carbon atom in the right and left positions respectively.

If this be true, then by the reduction of fruit-sugar, besides mannitol, a second stereo-isomeric alcohol might be obtained which must be sorbitol, corresponding to glucose.

This has been found to be the case. A 10 per cent. solution of crystallised levulose prepared according to Wohl's method (this Journal, 1890, 958) is cooled in ice and treated with $2\frac{1}{2}$ per cent. of sodium amalgam with continued shaking, dilute sulphuric acid is added from time to time so that during the first half of the experiment the solution is slightly acid and subsequently slightly alkaline. After about six hours the solution only slightly reduces Fehling's solution, it is thus just neutralised and evaporated on the water-bath until a large crop of sodium sulphate crystallises out, when it is extracted with eight times its volume of absolute alcohol; on concentration mannitol crystallises out. The resultant mass is extracted with 90 per cent. alcohol, and filtered from the undissolved mannitol. On evaporation there remains a colourless syrup, which on standing a few days partly crystallises. This is impure sorbitol; it is best purified by converting it into the benzoic aldehyde compound.

This compound closely resembles the corresponding compound from natural sorbitol. Sorbitol may be obtained from it which is in all respects identical with the natural body.

The two alcohols, sorbitol and mannitol, formed by the reduction of fruit-sugars appear to be produced in approximately equal quantities.

Both the alcohols yielded fruit-sugar on oxidation.

The reduction of fruit-sugar is the second reaction of the sugar group in which two stereo-isomeric bodies are formed which do not combine to form a third isomeric body. Wallach (Ann. 252, 166) obtained from levulimonene-nitrosochloride by piperidine, two isomeric nitrolamines, which most probably have the same structure but have a different optical activity. Dextro-limonene-nitrosochloride yields two similar bodies, each of which combines with one of the levo derivatives to form an inactive dipentene derivative. This may possibly be analogous to the two mannonic and the two gluconic acids.

—A. L. S.

Synthesis of a New Glucoside. E. Fischer. Ber. 23, 3687--3691.

MANY observers have obtained carbohydrates having a high molecular weight by the action of acids, &c. on glucose. The author has obtained a sugar, the properties of which show it to be analogously constituted to maltose, by the action of strong hydrochloric acid on glucose (dextrose). He proposes to call it iso-maltose. Pure glucose is dissolved in four times its weight of hydrochloric acid (sp. gr. 1.19), and the solution allowed to stand for 15 hours at 10° — 15° C. Ten times its weight of absolute alcohol is added to the solution; on the addition of an excess of ether the clear mother-liquor yields a colourless, amorphous precipitate, which is filtered out, washed with alcohol and ether and dried; it consists of a mixture of glucose, iso-maltose, and other bodies. It is dissolved in water, neutralised with soda and then slightly acidified with

acetic acid and the alcohol and ether expelled by evaporation. The cooled solution is fermented with beer yeast, which quickly destroys most of the glucose.

The impure solution of iso-maltose thus obtained is heated with phenylhydrazine acetate for about one hour, a little glucosazone is precipitated, the hot filtered solution deposits on cooling a yellow precipitate which is filtered off; on further heating the mother-liquor more glucosazone is deposited and the clear solution yields a further precipitate on cooling.

The precipitates obtained on cooling are purified by recrystallisation from water. $2\frac{1}{2}$ grms. of this product, which is iso-maltosazone, are obtained from 100 grms. glucose. The yield of iso-maltose is much greater, as there is considerable loss in the various operations.

The osazone has a composition corresponding to the formula $C_{12}H_{20}N_4O_6$, it melts at 150° — 153° . It is soluble in hot water, and differs in its melting point and crystalline form from maltosazone, and is much more soluble in hot absolute alcohol. It is decomposed by strong hydrochloric acid in the same way as other osazones, yielding phenylhydrazine and iso-maltosone. When heated with dilute hydrochloric acid, isomaltosone yields glucosone and glucose.

The condensation of glucose may also be effected by the action of a concentrated solution of phosphoric acid.—A. L. S.

Contributions to a Knowledge of the Pentaglucooses. W. E. Stone. Ber. 23, 3791--3798.

TOLLENS and the author (Ann. 249, 227) have previously described a method for the estimation of the pentaglucooses by determining the amount of furfural produced when pentaglucooses or bodies yielding them by hydrolysis are boiled with strong acids.

A series of analyses have been made by this method. The following percentage of furfural were obtained:—

	Per Cent.
Millet hay.....	3.34
" Timothy" (<i>Phleum pratense</i> L.)....	1.18
Wheat straw.....	4.16
Oats.....	2.29
Maize.....	2.89
Clover hay.....	1.55
Maize spike (without the corn).....	8.46
Flour from the whole of ditto.....	0.59
Maize bran.....	1.80
Oatmeal.....	0.49
Malt acrospire.....	1.82
Wheat bran.....	3.51
Brewers' grains.....	7.20
Linseed meal.....	1.27
Cotton seed husks.....	3.66
Beetroot slices.....	3.59
White lupin seeds.....	0.35
Yellow lupin seeds.....	1.69
Sweet orange peel.....	1.85
Water melon peel.....	2.70
Strawberries.....	1.95
Horned cattle dung.....	3.94
Peach tree gum.....	4.81
Cherry tree gum.....	5.73
Gum tragacanth.....	5.88
Gum Arabic.....	5.46

The following also gave small quantities of furfural, but not an estimable quantity.

Cotton-seed cakes, maize meal, sweet potatoes, sweet orange pips, coffee beans, buckwheat, beans.

The cupric reducing power of arabinose and xylose were determined. Arabinose ($[\alpha]_D = 104.1$) gave the following results:—70 cc. of boiling Fehling solution were mixed with 25 cc. of arabinose solution and heated for 4 minutes; the precipitated cupric oxide was then filtered out by a Soxhlet tube and washed with water, alcohol, and ether, and reduced in a stream of hydrogen to the metal.

One grammme of arabinose in a—

1	per cent. solution reduced	1.945	grms. of copper
$\frac{2}{3}$	" "	1.929	"
$\frac{1}{3}$	" "	1.958	"
$\frac{1}{4}$	" "	2.009	"

In the same way 1 grm. of xylose ($[\alpha]_D = 18.41$) in a—

1	per cent. solution reduced	1.864	grms. of copper
$\frac{2}{3}$	" "	1.841	"
$\frac{1}{3}$	" "	1.900	"
$\frac{1}{4}$	" "	1.959	"

Up to the present all attempts to ferment arabinose or xylose by yeast have failed. The author attempted to ferment xylose both alone and mixed with an equal weight of cane sugar, and in all cases not the slightest trace of fermentation of the xylose was noted.—A. L. S.

Studies on Starch. II.—On Gallisin and its Formation.

C. Scheibler and H. Mittelmeier. Ber. **24**, 301—305. (See also this Journal, 1890, 1140.)

GALLISIN, the unfermentable residue of commercial starch sugar, may be obtained by fermenting away the dextrose by yeast and precipitating the gallisin from the concentrated residue by alcohol. Its properties have been investigated by many observers; it forms a white hygroscopic powder, which easily reduces Fehling's solution, and on heating with dilute acids yields dextrose.

The authors have prepared gallisin in the above manner, purifying it by repeated precipitations of the concentrated solution with alcohol. The body thus obtained is neutral to litmus paper, and reduces Fehling's solution strongly. This they consider to show that gallisin contains a sugar.

By heating a solution of gallisin with phenylhydrazine acetate, a yellow solution is obtained, which on cooling gives a precipitate of a large amount of yellow osazone, which is purified by recrystallisation from hot water. It closely resembles the osazones of the saccharoses, and on analysis gave numbers corresponding to the formula $C_{21}H_{22}O_8N_4$. It is a little soluble in ether and acetone, more soluble in hot alcohol, from which the greater part is deposited on cooling. It is more soluble in hot water than the other osazones of the same composition. It melts between 152—153°.

From the composition of the osazone, it follows that gallisin contains a sugar having the formula $C_{12}H_{22}O_{11}$, and from the fact that it yields only dextrose on hydrolysis, and easily reduces Fehling's solution, it contains two dextrose nuclei, of which one contains an unaltered aldehyde group.

In their previous communication (Ber. **23**, 3060; this Journal, 1890, 1140), the authors have stated that this sugar is probably an intermediate product between starch cellulose and dextrose; but they now find that this is not so, for the amount of this sugar present during the hydrolysis of starch is least at the commencement of the reaction, and continues to increase as long as the action of the acid goes on. This indicates that the new sugar is formed by the action of the acid on glucose, and this is found to be so.

Fifty grms. of pure glucose and 500 cc. of 2½ per cent. sulphuric acid are heated for 12 hours on the water-bath; the acid is then removed by baryta, and the solution heated with phenylhydrazine acetate. A large crop of glucosazone separates, and on cooling the filtered solution a small amount of another osazone is obtained. One-fifth of a grammme of the purified osazone was obtained, and was found to be identical with that obtained from gallisin.

From the close resemblance of this osazone to that described by Fischer (see above), which he obtained from the sugar (iso-maltose) produced by the action of concentrated hydrochloric acid on glucose; there is no doubt that they are identical, and there appears to be no reason for considering that the sugars yielding them are not identical.

The authors are continuing their researches on the condensation of the hexaglucooses by means of metallic salts, &c., and hope shortly to publish further results.

Growth of Improved Varieties of Potato for Distilleries in France. A. Girard. Compt. Rend. **111**, 795—797.

THE author reports the results of two experiments made on the large scale in collaboration with practical distillers. In the first trial, 70,000 kilos. of the "Chardon" variety of potato, containing only 16 per cent. of starch, yielded 11.17—11.20 litres of absolute alcohol per 100 kilos, both when worked alone and when mixed with one-sixth of maize, with a view of enriching the dregs. In the second trial, 100,000 kilos. of Richter's Emperor potato, containing 20.9 per cent. of starch, furnished 14.33 litres absolute alcohol per 100 kilos.; a yield at least equivalent to that obtained from 40 kilos. maize or 250 kilos. beet. A crop of 30,000 kilos. Emperor potatoes per hectare would yield 4,300 litres alcohol per hectare, a result never hitherto obtained. The phlegms are of good quality, and the spirit easy of rectification. The distillery dreg from potatoes contains water, 91.80; soluble matter, 3.23; insoluble matter, 1.90 = 100.00.

The soluble matter is made up of glucose, 0.22; dextrin, 0.72; nitrogenous matter, 0.46; other organic matter, 1.41; ash, 0.42. The insoluble matter is made up of fat, 0.04; cellulose, 1.49; nitrogenous matter, 0.32; ash, 0.05. According to the scale adopted in Germany this would be worth 0.86 fr. per hectolitre, the dreg from maize distilleries being worth 1.57 fr. per hectolitre. As 100 kilos. potatoes yield 1.8 hectolitres dreg, the return from this source is 1.54 fr. per 100 kilos. Eighty head of cattle were fed for two months on a ration of 50 litres of this dreg together with beetroot pulp and hay. It was relished by the animals, who thrived and even fattened on it. The author concludes that potato distilleries would succeed as well in France as elsewhere.—J. M. H. M.

PATENTS.

An Improved Process of Fermentation. S. Joseph and H. Citron, Berlin, Germany. Eng. Pat. 4746, March 26, 1890. 4d.

In this process fermentation is carried on in closed vessels under greatly reduced pressure, by which means much less yeast is required to start the fermentation.—H. T. P.

An Improved Fermenting Process for Beer, Wine, and other Fermentable Liquids. J. Salomon, Brunswick, Germany. Eng. Pat. 5673, April 15, 1890. 4d.

THE invention consists in sterilising the fermentable liquid after the first fermentation by heating it to 80° C. in a suitable vessel, a second fermentation being afterwards effected by the addition of as pure a yeast as is obtainable. Either "top" or "bottom" yeast may be employed. By the above process a much greater stability is conferred on beers, and when required for transport there is no necessity for storing them at a temperature near freezing point. After the first or second fermentation the liquid may be saturated with carbonic acid.—H. T. P.

Improvements in Apparatus for the Production of Yeast and Similar Substances. H. H. Lake, London. From A. Joergensen, Copenhagen, Denmark, and A. Bergh, Stockholm, Sweden. Eng. Pat. 6220, April 23, 1890. 8d.

THIS apparatus is mainly intended for the continuous development of large quantities of pure yeast. It consists of an upper and a lower cylinder, which communicate by

means of a pipe and cock. Each cylinder is provided with a helical agitator, and with pipes and taps for the admission of filtered air. The lower cylinder is fitted with a steam and water jacket. The level of the wort in the lower vessel is indicated by a float, which actuates a pointer outside the apparatus. The wort, preferably already sterilised, is introduced into the lower cylinder, or it may be there sterilised by passing steam through the outer jacket. The wort is then cooled and aerated by means of filtered air which is forced in at the bottom of the cylinder through a pipe provided with a number of holes. A portion of the wort is next forced into the upper cylinder where it is inoculated with a pure yeast-cultivation from the laboratory. This wort is then passed back into the lower cylinder, or it may be left in the upper one, according to circumstances. This yeast may be removed either when the fermentation has reached its highest stage, or when the yeast formed has settled. In either case sufficient fermenting wort must be left in the upper cylinder to start a fresh fermentation. After the removal of the yeast from the lower chamber the latter is cleaned, sterilised, and charged with fresh sterilised wort, which is then infected with the wort from the upper cylinder. The upper cylinder is subsequently cleaned and sterilised in its turn, and so on.—H. T. P.

Improvements applicable to the Manufacture of Pure Grape Spirit, and Apparatus used for the Same or other Spirits, and also the Ageing of the Same. P. L. F. E. Vignier, London. Eng. Pat. 20,430, December 15, 1890. 1s. 3d.

In order to obtain an improved wash for distillation, concentrated grape juice imported from wine countries, is mixed with tartaric acid, tannin, and other ingredients to render the wort suitable for the production of fine spirit, and diluted to such an extent that the wash after fermentation may contain from 10—20 per cent. of proof spirit. The bouquet of the Charentais district is imparted to the wash by employing for pitching a wine yeast obtained from the said district. Distillation is carried on in three stages, during which "weak low wine," "strong low wine," and finally rectified spirit are obtained. For drawings and description of the distilling apparatus employed the original specification must be consulted.

The ageing of the spirit is effected by blowing through it filtered air heated to 160° F., and it is proposed to complete the ageing by a current of ozone.—H. T. P.

Improvements relating to the Manufacture of Fermented Liquids, and to Apparatus therefor. H. H. Lake, London. From H. Götter, Jersey City, U.S.A. Eng. Pat. 20,985, December 23, 1890. 8d.

THE rapid fermentation of wines is effected by suspending in the fermenting vessels some inert body exposing a large surface, as, for instance, spun glass or asbestos. For the rapid production of sparkling wines a special apparatus is employed. The must in which fermentation has already commenced is charged into a vat which is placed inside a strong closed metallic vessel capable of withstanding a pressure of 120 lb. per sq. in. A number of woollen bags containing spun glass are suspended in the vat from rods radiating from a central standard. Fermentation is carried on at a temperature of 70°—80° F. until a pressure of 75 to 90 lb. per sq. in. is attained, when fermentation is considered to be complete. Five to six days are required for this purpose. The wine is then run into a receiver common to several fermenting vessels, and from thence through refrigerators and filters charged with some inert filtering material, to bottling machines. Air is excluded during the whole of the operation, the pipes, &c., being filled with water or carbonic acid. The spun glass is rinsed with water after each fermentation, and periodically it is thoroughly washed and heated to purify it. For drawings and details of apparatus the original specification must be referred to.—H. T. P.

Improvements in the Manufacture of Extract of Hops. A. J. Boulton, London. From O. Schweissinger, Dresden, and L. Hoffmann, Hamburg, Germany. Eng. Pat. 853, January 16, 1891. 4d.

THE process consists in separating the lupuline (hop-dust) from the hop leaves by sifting and extracting each separately—the hop leaves with water and the lupuline with a mixture of 10 parts of ether and 90 parts of alcohol, or either solvent may be used alone. The extracts are concentrated to a syrupy consistency at as low a temperature as possible, the aqueous solution being evaporated in vacuo. Finally, the residues are mixed and preserved in vessels in which the air is displaced by carbonic acid in order to prevent oxidation of the extract. This hop extract is claimed to be perfectly soluble in cold water.—H. T. P.

XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, AND DISINFECTANTS.

(A.)—CHEMISTRY OF FOOD.

Note on the Action of Meat Extracts on Certain Metals. Balland. Compt. Rend. 111, 895.

Tin and lead, and their alloys, are slowly attacked by the weak acids contained in canned meats, the amount of action being proportional to the surface in contact. The tin used for the manufacture of tin-plate contains 1—2 per cent. of copper and other metals, besides traces of lead, and offers greater resistance to the acids present in preserved meats than does pure tin or tin containing much lead. The author is of opinion, seeing that such tin is adapted for soldering purposes, that the use for sealing meat-tins of the quality of tin employed by tin-plate manufacturers should alone be tolerated.—E. B.

PATENTS.

Improved Apparatus to be Used for the Purification of Water. A. Dervaux, Brussels, Belgium. Eng. Pat. 9756, July 4, 1888. (Amended April 30, 1890.) 8d.

THE amendments mainly relate to the abandonment of the claim for the particular form of "decanter" with hydraulic or rivetted joints embodied in the earlier patent, and the application of mechanical agitation to aid the saturation of water with lime or other material also previously claimed.

—B. B.

Improvements in Apparatus employed in Treating Sewage. W. Warner, Nottingham. Eng. Pat. 1623, January 30, 1890. 8d.

PRECIPITATION processes for treatment of sewage need some simple means of regulating the quantity of the precipitants added to the water or sewage and of mixing

them therewith. These objects are attained by the patentee by feeding the chemicals to be used through a hopper on to grinding rollers whence they pass into a tank provided with a vertical shaft carrying propeller blades which serve to mix the contents. The flow of sewage through the tank is controlled by a cock, and as it leaves the tank it carries with it a pre-determined amount of the precipitant for treating the main quantity of sewage.

A second device of the patentee is the use of dished plates for filter presses, the object being to avoid the breakages that occur with flat plates consequent on the unequal contraction during their cooling after casting. A third claim is for a rack and pinion arrangement for closing the end plate, and another is for a cylinder provided with a four-way cock for moving the end plate when compressed air, water, or steam is used.—B. B.

Improvements in Apparatus for Sanitary Disinfection and other Purposes. A. M. Clark, London. From C. L. Cohn, New York, U.S.A. Eng. Pat. 19,670, December 2, 1890. 8d.

THE apparatus patented consists essentially of a reservoir of some disinfecting liquid such as a solution of zinc chloride which is kept filled from a larger reservoir in such a manner as to ensure the head of liquid in the smaller reservoir being constant. The liquid oozes through a tubulus, in the lower part of the smaller reservoir, which is packed with fibres of asbestos or spun glass arranged longitudinally; the rate of flow of the liquid is controlled by loosening or tightening an elastic washer encircling the bundle of fibres. A continuous and regular supply of disinfectant is thus obtained. On leaving the reservoir the disinfectant meets a constant stream of water with which it mingles and flows to its point of application. The valve controlling the supply of water is arranged so that it is raised further from its seat at intervals when the apparatus is used, and any possible accumulation of grit dislodged. Combined with the reservoir of disinfectant is an "atomiser" actuated by the same motion that performs the flushing action just mentioned, which diffuses at the instant of use a spray of a solution of thymol or similar material into the air of the room.—B. B.

(C).—DISINFECTANTS.

PATENT.

An Improved Process for rendering Tar Oils Soluble in Water and the Production of Disinfectants and other Useful Products therefrom. W. Dammann, Halle, Germany. Eng. Pat. 1017, January 20, 1890. 6d.

TAR oils containing such bodies as phenol and cresol are said to be rendered soluble in water in the following manner.—

A fat or fatty oil such as linseed oil or a resin is mixed with the tar oil and the mass treated with caustic alkali in presence of alcohol until saponification is complete. The product is said to be homogeneous and soluble. "Certain tar oils, especially those rich in carboic acid, are already rendered soluble by simply mixing them with soaps."

The fat itself, the tar oil, or a mixture of the two may be treated so as to introduce a halogen, sulphur, phosphorus, or arsenic, or other elements, or a radical such as NO₂ or NH₂ or SO₂ into the product, which is rendered soluble in the manner already described.

"The tar oils soluble in water and thus produced have the appearance of a thick but clear or dark brown oily liquid or semi-plastic mass which is clear and transparent. In this form it can be used as a disinfectant, and is to be termed 'Lysol' or 'Lysoline.'" (See this Journal, 1890, 1136.)—B. B.

XIX.—PAPER, PASTEBOARD, Etc.

PATENTS.

Improvements in the Moulds Used on the Sembritzki Patent Machine and any Machine for Mechanically Making Hand-made Paper, and in other Paper-Making Moulds. W. Green, London. Eng. Pat. 1713, February 1, 1890. 6d.

IN connexion with the moulds now in use for the Sembritzki patent machine (Eng. Pat. 4077 of 1883) for mechanically making hand-made paper, light metal mould frames with the required sheets already attached to them are applied by the patentee. These light frames are affixed by means of screws to the top of the moulds now in use, thus obviating the tedious operation of sewing and unsewing, and soldering and unsoldering the sheets.—H. S.

Improvements in Lining Boilers or Digesters Used in the Manufacture of Paper-Pulp and for similar Purposes. C. Kellner, Vienna, Austria. Eng. Pat. 6951, May 6, 1890. 4d.

ON the internal surface of iron or steel boilers or digesters, after they have been thoroughly cleaned, a coating is applied consisting of blue slate ground to powder and mixed with a suitable quantity of a solution of silicate of soda. Then a second coating is added, consisting of equal quantities of ground slate and Portland cement, and finally the whole is covered with a paste of Portland cement. In some cases the intermediate coating may be dispensed with. This compound lining is said to resist the action of corrosive acids and alkalis under great heat, and also to adhere firmly to the boilers or digesters without any liability to crack or become detached.—H. S.

Improvements in the Use and Application of Nylomite, Celluloid, and the Like. G. L. Auders and C. H. Elliot, London. Eng. Pat. 17,012, October 24, 1890. 4d.

FIXED designs or "reading matter" are printed, embossed, or otherwise prepared on cardboard, paper, wood, ivory, metal, &c., and afterwards coated upon either or both sides with nylomite, celluloid, or similar substances, hereby imparting to the design, &c. a high degree of finish, and rendering it perfectly waterproof.—H. S.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

Further Improvements in the Utilisation of Atmospheric Oxygen. G. Kassner. Dingl. Polyt. J. 278, 468—478. (See also this Journal, 1890, 187.)

THIS paper refers to the manufacture of oxygen by means of the ortho plumbates of calcium, barium, and strontium, the fundamental reactions being—

This reaction is best performed at a dark-red heat. The calcium plumbate so formed is afterwards decomposed with carbonic acid, at a bright red heat, and oxygen is given off.

Calcium plumbate is obtained by igniting an intimate mixture of lead oxide and calcium carbonate, the latter being employed in a pure form (calc spar or precipitated chalk) and preferably 5 per cent. in excess of the equivalent quantity. The dry mixture can be furnace straight away, but a better decomposition and a more porous product is

obtained by damping the mass, adding starch, milk of lime, tar, or sugar, and forming the same into bricks. There may be added substances, such as charcoal, sawdust, ammonium carbonate, straw, which on igniting volatilise, leaving a porous mass behind. The bricks are now burnt in a current of air, preferably with generator gas, and the products of combustion are drawn off the kiln by means of an air-pump. The calcium carbonate gives off its carbonic acid at comparatively low temperatures, in presence of lead oxide; the lead oxide is hereby first of all reduced to metallic lead, which on raising the temperature is again oxidised and finally converted into lead peroxide.

Whilst this operation is performed in one series of kilns, the calcium plumbate in another series is treated, along with steam, with the carbonic acid given off in the first operation, or with flue gases, at a temperature not exceeding 95° C. The first kiln of this series is brought finally to a bright red heat and treated with a small quantity of pure carbonic acid. Oxygen is given off and it is driven out completely by means of superheated steam.—H. A.

Piperazine. W. Majert and A. Schmidt. Ber. **23**, 3718—3723; and Ber. **24**, 241—243.

By means of a new method of purification the authors have succeeded in obtaining Ladenburg's "ethylene-imine" in pure condition from ethylenediamine hydrochloride, and find that it is identical with Hofmann's diethylenediamine. The base has the melting point 104°—107°, and the boiling point 135°—138°, and is almost certainly identical with Ladenburg's compound, although the latter gives the melting point as 159°—163°; this is probably due to the fact that the base had been converted into the carbonate by the carbonic acid present in the air. Piperazine has neither caustic nor toxic properties, but dissolves uric acid even in large excess, forming, however, always the neutral salt, $C_4H_{10}N_2 \cdot C_3H_5N_3O_3$.

A direct comparison of Schreiner's spermine with piperazine has shown that these compounds are not identical, great differences being observed in the phosphates and double bismuth iodides of both bases.—H. G. C.

Piperazine or Diethylene-di-imine. A. Ladenburg. Ber. **23**, 3740—3741.

THE author has prepared the dibenzoyl compound of the diethylene-di-imine obtained from ethylenediamine (Ber. **22**, 2706) and finds that it is identical with the dibenzoyl compound of diethylenediamine recently prepared by v. Hofmann, a further proof of the identity of the two bases.

—H. G. C.

Nicotine. A. Pinner and R. Wolfenstein. Ber. **24**, 61—67.

NICOTINE is slowly oxidised by hydrogen peroxide, especially in presence of platinum sponge, a basic body of the formula $C_{10}H_{12}N_2O$ being formed. This so-called oxy-nicotine has resulted by the replacement of two hydrogen atoms in nicotine ($C_{10}H_{14}N_2$) by one atom of oxygen. The oxidation, which takes several weeks, is carried on until there is no longer any smell of nicotine, and the product of the reaction concentrated in vacuo, when a yellow oil remains behind which can be purified by dissolving in alcohol and removing the solvent in an exsiccator. On prolonged standing the oil solidifies to a crystalline mass, but it is too hygroscopic to allow of its being analysed. Of its salts the platinum double chloride and the picrate are the most characteristic and can be obtained in a crystalline form. The first of these separates as an oily mass when an excess of platinum chloride is added to the base, but on standing it becomes crystalline. It cannot be recrystallised owing to its readily undergoing decomposition when in solution. The picrate, which also first forms as an oil, can be recrystallised from water and melts at 154°—158°. Analyses of both these

salts are given, which point to the above formula, $C_{10}H_{12}N_2O$, for the base. The picrate has the composition—

and corresponds to the picrate of nicotine—

which latter forms difficultly soluble needles, melting at 218°. The mercuric chloride double salt of the oxidation product forms an amorphous white precipitate. The "orynicotine" is readily soluble in water and in alcohol, insoluble in ether. It is not volatile with steam, and is not decomposed when distilled with caustic alkali. When oxidised with potassium permanganate, nicotinic acid (β -pyridine carboxylic acid) results. It possesses a slight mushroom-like smell and has a similar though less marked physiological action than nicotine.

With the view of obtaining evidence of the presence of an amido group in nicotine, the base was treated with sodium nitrite to form a nitroso-compound, and also with acetic anhydride, but in both cases without result. The latter reagent reacts on nicotine in a closed tube at 150°—170°, but the nature of the decomposition has not yet been worked out.

Benzoyl chloride reacts upon nicotine on warming; the resulting products appear to be different from that obtained by Will by bringing nicotine and benzoyl chloride together in ethereal solution (Ann. Chem. Pharm. **118**, 206), but they are still under investigation.

These experiments are being continued with the view of elucidating the constitutional formula of nicotine, a summary of the present state of knowledge on the subject being given in the paper.—C. A. K.

Preparation of Lecithin from Plant Seeds. E. Schulze and A. Likiernik. Ber. **24**, 71—74.

LECITHIN occurs widely distributed in the vegetable kingdom, and is found in the ethereal extracts of plants side by side with glycerides, wax-like products, cholesterol, &c., but up to the present it has not been isolated from such mixtures.

In order to separate the lecithin the following plan was adopted: Finely-powdered plant seeds (vetch and lupin) were first extracted with ether, when only a portion of the lecithin goes into solution. The insoluble residue was then digested with alcohol at 60° C. (in some cases a little alkali was added to neutralise the free acid contained in the seeds), whereby the bulk of the lecithin is dissolved in a fairly pure state. In order to purify the product thus obtained, the solvent was distilled off at 40°—50° C. and the residue treated with cold ether. The lecithin dissolves, and by shaking the solution thus obtained with water the impurities are taken up by the latter. An emulsion, however, forms on shaking the mixture, and crystals of common salt must be added to clear the ethereal solution. This clear solution, when gently evaporated, left a residue of lecithin, which was further purified by dissolving it in alcohol (absolute) and again concentrating. The lecithin separates as a pale yellow product, possessing the characteristic properties of this body; it could not be obtained in a crystalline form. When saponified by baryta water, cholin, glycerol phosphoric acid and fatty acids result, which were separated and identified. Both solid fatty acids and oleic acid were found in the products of saponification, so that the lecithin from plants, like that got from the yolk of eggs, appears to be a mixture of several lecithins. This presence of lecithin in the seeds of plants leads to an error in the determination of the fat contained by extraction with ether, as the lecithin also goes into solution, though to a varying extent. The error is small in the case of seeds rich in fatty matter, but when the ether extract only amounts to about 2 per cent. and the per cent. of lecithin reaches 1.2 to 1.3, as in the seeds of the vetch and of the pea, the error is very considerable, and a determination of the phosphorus in the residue should be made and the quantity of extract free from lecithin thus obtained.—C. A. K.

The Ethereal Oil of Asafetida. F. W. Semmler.

Ber. 24, 78—81.

THE author has examined the constituents of fractions II. and III. of this oil, obtained by simple distillation of the oil (this Journal, 1891, 157).

The second fraction of boiling point $80-85^{\circ}\text{C}$. under a pressure of 9 mm. has a specific gravity of 0.9721 at 15° , and is laevo-rotatory. It consists entirely of one product having the formula $\text{C}_{11}\text{H}_{18}\text{S}_2$, as shown both by analysis and by a vapour density determination. In its behaviour it appears to be a disulphide, containing one saturated and one unsaturated radicle. It boils with slight decomposition at $210-212^{\circ}$, forms a crystalline compound with mercuric chloride, $\text{C}_{11}\text{H}_{18}\text{S}_2 \cdot 2\text{HgCl}_2$, and when treated with zinc-dust yields a monosulphide $\text{C}_{11}\text{H}_{18}\text{S}$. It constitutes about 45 per cent. of the crude oil. The third fraction, which boils at $120-130^{\circ}\text{C}$. under a pressure of 9 mm., has a specific gravity of 1.0120 at 15° , and is laevo-rotatory. It consists also of a disulphide having the formula $\text{C}_{11}\text{H}_{18}\text{S}_2$, and when treated with zinc-dust yields the corresponding monosulphide $\text{C}_{11}\text{H}_{18}\text{S}$. With mercuric chloride precipitates of varying composition resulted, but could not be separated on account of their insolubility in alcohol. When distilled under the ordinary pressure it decomposes, evolving gases having an unbearable smell. The constituents of the ethereal oil of asafetida are therefore the following:—

(1.) Two terpenes. (2.) An oxygenated body ($\text{C}_{15}\text{H}_{24}\text{O}$)* from which the sesquiterpene $\text{C}_{15}\text{H}_{24}$ is derived. (3.) A disulphide $\text{C}_{11}\text{H}_{18}\text{S}_2$. (4.) A disulphide $\text{C}_{11}\text{H}_{18}\text{S}_2$.

—C. A. K.

Kuroumi Oil. W. Kwasiak. Ber. 24, 81—82.

THIS is the ethereal oil of the leaves of *Lindera friciia*, occurring in Japan. The oil is of a deep yellow colour, and possesses a powerful aromatic odour; the specific gravity of the oil is 0.901 at 18°C . By fractional distillation and treatment with sodium two terpenes were isolated. One of these boiled between 175 and 180°C . was dextro-rotatory, and gave a tetrabromide melting at 104° ; it was thus dextro-limonene. The other boiled above 180° , was optically inactive, and gave a tetrabromide melting at 124° , a nitroso-chloride melting at 101° ; it was dipentene. Besides these terpenes were found terpineol, $\text{C}_{10}\text{H}_{18}\text{O}$, and carvol, the former optically inactive, the latter laevo-rotatory. Terpineol was identified by the action of hydrochloric acid and bromine, and by means of its iodide, which melts at $75-76^{\circ}$. The carvol is distinguished from the dextro-rotatory carvol of oil of caraway only by its optical properties.—T. L. B.

Lupol. A. Elkiernik. Ber. 24, 183—186.

ETHER extracts from the husk of the seed of *Lupinus luteus*, a crystalline body, which does not give the reactions of cholesterol. This new substance the author proposes to term *lupol*.

In order to isolate it the husks were extracted with ether and the extract saponified by alcoholic potash; after evaporation of the alcohol the residue was shaken with water and ether. The ethereal layer was removed and distilled, whereby a crystalline mass consisting chiefly of lupol was obtained. The benzoate was next obtained by fusion with benzoic anhydride, and recrystallisation; this was then decomposed by heating with alcoholic potash when lupol was obtained pure.

It is insoluble in water, easily soluble in ether, chloroform, benzene, petroleum ether, and carbon bisulphide, and likewise in hot alcohol. It crystallises from alcohol in long colourless needles. It gives the following characteristic reaction.—By dissolving a small quantity in about 5 cc. of chloroform and adding a few drops of acetic anhydride, and a couple of drops of concentrated sulphuric acid, a reddish colouration is obtained, turning in the course of half an hour to an intense violet red. Lupol is dextro-rotatory, a chloroform solution showing $[\alpha]_{\text{D}}^{20} = +27^{\circ}$. The melting point was found to be 204°C . On heating it volatilises with partial decomposition, giving rise to an odour reminding

of Russia leather. Elementary analysis agreed with the formula $\text{C}_{28}\text{H}_{46}\text{O}$, but $\text{C}_{28}\text{H}_{46}\text{O}$ and $\text{C}_{27}\text{H}_{44}\text{O}$ are also possible. Analysis of lupol itself, of the acetate, and of the benzoate indicated a lower percentage of hydrogen in lupol than is contained in cholesterol. The acetate melts at 230° and the benzoate at 250° .—T. L. B.

Some Constituents of the Seed Husks of Pisum Sativum and Phaseolus Vulgaris. A. Likernik. Ber. 24, 187—188.

FROM the seed husks of *Pisum sativum* the author has isolated a body corresponding in properties with the phytosterin of Hesse (1878) (Ann. 192, 175); *Phaseolus vulgaris* yielded, by the method used for obtaining cholesterol, a quantity of material which on fractional crystallisation from alcohol yielded two substances, one of which was laevo-rotatory, and the other dextro-rotatory; to the former the author gives the name *paraphytosterin*, and to the latter the name *phasol*. The first is a member of the cholesterol group; it crystallises from alcohol in broad shining leaflets. It differs from all other cholesterolins, however, in that it melts at $149-150^{\circ}\text{C}$, and also in that the crystals of its benzoate are dull and not shining. For paraphytosterin in chloroform $[\alpha]_{\text{D}}^{20} = -44.1^{\circ}$. Elementary analysis agrees with $\text{C}_{24}\text{H}_{36}\text{O}$ or $\text{C}_{26}\text{H}_{44}\text{O}$ or an intermediate formula.

Phasol crystallises from alcohol in small shining tablets, melting at $189-190^{\circ}$. The chloroform solution showed $[\alpha]_{\text{D}}^{20} = +30.6^{\circ}$. Elementary analysis agrees with $\text{C}_{15}\text{H}_{24}\text{O}$.

The author concludes that it is quite possible that phasol may form a homologous series with cupreol, quebrachol, and α - and β -lactucol. Its chloroform solution shaken with sulphuric acid (sp. gr. 1.76) shows a purple colouration just as most of the cholesterolins do, but the colouration is somewhat weak.—T. L. B.

Olefinic Constituents of Ethereal Oils. F. W. Semmler.

Ber. 24, 201—211. (See also this Journal, 1890, 100, 889, 962, and 1145.)

Geranial, $\text{C}_{10}\text{H}_{16}\text{O}$ (geranium aldehyde, for whose preparation see this Journal, 1890, 1145), boils under a pressure of 760 mm. at a temperature of $224-228^{\circ}$, with slight decomposition. Its specific gravity is 0.8972 at 15° , compared with water at that temperature. It is optically inactive.

Determination of the molecular refractive power indicates the presence of two ethylene linkages.

Brominated in acetic acid, geranial takes up four atoms of bromine. The brominated compound may be separated as a hitherto uncrystallisable oil by addition of water.

By heating geranial to 170° for 20 minutes with potassium bisulphate, and then distilling with steam, an oil is obtained which, after rectifying over sodium, shows the boiling point $174-176^{\circ}$.

The molecular refraction points to the existence of three double linkages, so that the product must belong to the closed-chain series. All properties prove identity with cymol, $\text{C}_{10}\text{H}_{14}$, so that there is here a direct passage from a methane derivative to a benzene derivative, geranial belonging undoubtedly to the open-chain series. This is shown in the adjoining formula:—

Geranial.

Cymol.

Orange Oil.—Völekel (Ann. **39**, 120) states that this oil contains no oxygen, an assertion which the present author cannot support. The specific gravity of the oil at 20° C., compared with water at the same temperature, is 0.8435. If the oil be shaken with a saturated solution of acid sodium sulphite, and allowed to stand, crystals separate after the lapse of several weeks; on decomposing these with soda, and distilling with steam, an oil is obtained having the smell of oranges. Fractional distillation separates from this oil a portion boiling at 224°—228° and identical with geranial.

Citral.—The product which has been brought into commerce under this name, and which is contained in citron oil, in lemon-grass oil, and in citronella oil, is here shown to be identical with geranial. Geranial has been detected in a number of other ethereal oils, so that it is quite widely distributed in nature, and to it must be ascribed in great part the characteristic odour of the citron group.

Coriandrol is the name given by the author to the chief constituent of coriander oil.

It boils between 194° and 198° C. (under a pressure of 760 mm.) with slight decomposition. It is dextro-rotatory. From the molecular refraction there would seem to be present two double linkages, and with this the properties of the body are in agreement. Its empirical formula is $C_{10}H_{18}O$; four atoms of bromine are capable of absorption. Oxidation gives the compound $C_{10}H_{16}O$. Previous work on coriander oil has been done by Kawaller (Jahresh. 1852, 624), and Grosser (Ber. **14**, 2485).

Linalool is the chief product of linalool oil (see Morin, Ann. Chim. [5], **25**, 427). Its empirical formula is $C_{10}H_{18}O$, and it stands in close relationship to geraniol. It boils (at 760 mm. pressure) near 190° C., and possesses a specific gravity, at 20°, of 0.8702, compared with water at the same temperature. Two double linkages are indicated, and so an open chain.

German Balsam Oil contains an aldehyde, which appears to be identical with citronellol obtained from citronella oil. It has the empirical formula $C_{10}H_{18}O$. The investigation is still incomplete.

Olefinic Camphors is the term proposed by the author for compounds of the composition $C_{10}H_{16}O$, $C_{10}H_{14}O$, and $C_{10}H_{12}O$, which have no closed chain. They are, so far as can be at present judged, all liquid at ordinary temperatures, and possess a lower specific gravity than the isomeric camphors of the closed-chain series. They are either alcohols, aldehydes, or ketones, and are very widely distributed amongst the ethereal oils.—T. L. B.

Cytisine. K. Buchka and A. Magalhães. Ber. **24**, 253—261.

CYTISINE may be more readily prepared according to the following method than by Partheil's process (this Journal, 1891, 63): the ground laburnum seeds are extracted with dilute hydrochloric acid, the solution concentrated, made alkaline, and extracted with chloroform. On evaporating the latter, cytisine remains as a pale yellow oil, which quickly crystallises, and may be obtained almost colourless by repeated crystallisation from water. It melts at 156°, sublimes readily, is easily soluble in water, alcohol, and chloroform, sparingly in ether, insoluble in carbon bisulphide and light petroleum. Analysis and determination of the molecular weight have confirmed Partheil's formula, $C_{11}H_{14}N_2O$. It is a di-acid base, yielding two hydrochlorides, the first of which has the formula $C_{11}H_{14}N_2O \cdot HCl$, and forms colourless transparent monosymmetric crystals, whilst the second, $C_{11}H_{14}N_2O \cdot 2HCl + 2\frac{1}{2}H_2O$ forms small colourless hard crystals. Two platino chlorides, an auro chloride, and a double-zinc chloride have also been prepared.

On distillation with soda-lime, a distillate is obtained which contains pyrroline, and smells strongly of pyridine and quinoline bases. Potassium permanganate converts it into a syrupy acid, insoluble in ether.—H. G. C.

Hydrocotoïne, a Constituent of the Coto Bark. G. Ciamician and P. Silber. Ber. **24**, 299—301.

THIS compound was first obtained from coto bark by Jobst and Hesse (Annalen, **199**, 17). The authors obtained it by repeated crystallisation from alcohol, in long yellow needles melting at 98°, and soluble in ether, acetone, and acetic acid, insoluble in water. The analysis and determination of the molecular weight confirmed the formula $C_{15}H_{14}O_4$. It dissolves in caustic alkalis with a yellow colour, the alkaline compounds separating from concentrated solutions as oils. It is converted by hydrochloric acid at 130 into methyl chloride, benzoic acid, and a reddish-yellow compound soluble in sodium carbonate solution. It was found, by Zeisel's method, to contain two methoxyl groups, and also contains a hydroxyl group, as it yields an acetyl compound and takes up another methyl group on treatment with potash and methyl iodide, the trimethoxy-compound thus formed being insoluble in alkalis and giving only a yellow colouration with ferric chloride.

These results agree with the constitutional formula—

but further experiments are necessary before it can be regarded as proved.—H. G. C.

PATENTS.

The Manufacture of New Derivatives of Phenyl-amido-acetic Acid. B. Willcox, London. From the "Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 4382, March 20, 1890. 6d.

BENZOYL-PHENYL-AMIDO-ACETIC acid results on treating phenyl-amido-acetic acid with benzoyl chloride in presence of alkali. It is separated from the product of the reaction by the addition of acid, and is purified by boiling with hydrochloric acid and water successively, being finally recrystallised from alcohol. It forms white needles very difficultly soluble in water, and melting at 175.5° C. Treated with phenol, and a dehydrating agent, such as phosphorus oxychloride, this benzoyl compound yields a phenyl ether of benzoyl-phenyl-amido-acetic acid, which can be purified by recrystallisation from dilute alcohol. When boiled with alkali, the ether forms what appears to be an anhydride—a body of melting point 101° C. This also results when heat is applied in the preparation of the phenyl ether.—C. A. K.

Production of Guaiacol Ether. C. Murray, London. From the "Farbwerke vormals Meister, Lucius, und Brüning," Hoechst-on-the-Maine, Germany. Eng. Pat. 5366, April 8, 1890. 4d.

CRUDE guaiacol of boiling point 200°—205° is converted into a salt, preferably the potassium salt, which is purified by recrystallisation from alcohol; this is then employed for the preparation of a benzoyl compound by treatment with benzoyl chloride on the water-bath. The resulting body, for which the name of "Phthiosot" or "Benzosol" is proposed, is difficultly soluble in water, nearly insoluble in glacial acetic acid, readily soluble in chloroform, ether, and in hot alcohol. It melts at 50°, and when pure has neither taste nor smell, these last qualities being of advantage in its employment for medicinal purposes.—C. A. K.

The Manufacture of Diquinolylne Derivatives. B. Willcox, London. From the "Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 5722, April 15, 1890. 6d.

A METHOD for obtaining diquinolylne derivatives by treating amidophenylquinoline or the alkylated derivatives of amidophenylhydroxyquinoline with aceto-acetic ether in the cold. On heating these substances subsequently to 200°—250° C. with or without condensing agents they are converted into two isomeric hydroxym-thyldiquinolylnes or alkylated

hydroxy derivatives of these bodies. The two isomers obtained from amidophenylquinoline (Ber. 18, 1904) are the α - and β -hydroxymethylquinolylines. The former crystallises without water, turns brown at 340° C. without melting, and its hydrochloride contains 3 H₂O. The salt is turned yellow by cold water and decomposed into basic salt. The β -modification crystallises with 1 H₂O, and melts when anhydrous at 312° C. Its hydrochloride contains 3 H₂O, and is not decomposed by water. A further example is also given of the formation of similar bodies from *m*-amidophenyl-*p*-methoxyquinoline (Ber. 20, 1920). By condensing this substance with aceto-acetic ether in the cold, and subsequently heating the product to 200—250° C., two bases are formed which differ by the solubility of their sulphates in hot dilute sulphuric acid. The β -compound, which gives the less soluble sulphate, yields a base having a melting point above 320° C. and appears to be methoxyhydroxymethylquinolylines. On reduction with tin and hydrochloric acid or sodium and alcohol it yields a hydride of which the base melts at 265°. Its sulphate has a bitter taste similar to that of quinine sulphate, and has the same physiological properties in cases of intermittent fever. The α -isomeride forms a sulphate readily soluble in hot dilute sulphuric acid, and the base which crystallises in shining tablets loses water of crystallisation at 130—140° C. On reduction it gives a tetrahydride melting at 140° and forming more soluble salts than the β -base. The hydrochloride is sparingly soluble in dilute hydrochloric acid.—T. A. L.

Improvements in the Manufacture of Phenacetine Derivatives. B. Willeon, London. From the "Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 5723, April 15, 1890. 6d.

ALKYLATED phenacetines result by treating phenacetine first with metallic sodium and then with an alkyl haloid. The sodium is added to a solution of phenacetine in xylene, when the sodium compound separates in white needles; the whole is then treated with the alkyl iodide or bromide, the resulting sodium salt removed by filtration, the xylene distilled off with steam, and the residue dried and then distilled either under ordinary or reduced pressure. The methyl compound distils at 295—305° C. as a colourless oil, which solidifies on cooling to a crystalline mass, which can be further purified by crystallisation from ether or from petroleum ether. It is moderately soluble in water, readily in ether, and melts at about 40° C. The ethyl compound is difficultly soluble in water, moderately so in ether; it melts at 36° and boils at 298° C.

Its formation is represented by the following equation:—

The products are valuable for pharmaceutical purposes. —C. A. K.

Method of and Apparatus for Treating Atmospheric Air to obtain Oxygen therefrom. E. Neave, Sydney, New South Wales. Eng. Pat. 6463, April 28, 1890. 6d.

Air is drawn by means of pumps through a separator; this is a porous clay cylinder fitted externally with a thin india-rubber jacket and packed internally with specially prepared porous caoutchouc. When the separator is exhausted much more oxygen than nitrogen passes through the porous membranes, and this, after being forced through some vessels filled with calcium hydrate and others with water to still further eliminate the nitrogen, is received in suitable gas-holders. The porous rubber is prepared by first dissolving caoutchouc in naphtha, evaporating this off, and again dissolving in a mixture of naphtha and oil of turpentine, the india-rubber being then left on a second evaporation in a spongy state. The specification is illustrated by a drawing. —S. G. R.

XXII.—EXPLOSIVES, MATCHES, Etc.

The Propagation of the Explosive Wave in Liquids and Solids. D. Berthelot. Compt. Rend. 112, 16—27.

The propagation of the explosive wave in gases has been already established by Vieille and the author to be subject to the primary laws of undulatory phenomena such as sound. The maximum rate attained is 2,800 m. per second, and depends on the heat developed, corresponding to the total quantity evolved by the reactions that accompany detonation, and which occur too rapidly to be appreciably diminished by loss by radiation, conduction, or even dissociation.

In order to elucidate his more recent work on the propagation of the explosive wave in liquids and solids, the author gives a *résumé* of the experiments with gaseous media already alluded to, and recorded in his book "Sur la force des Matières Explosives." It is there shown that the rate of the explosive wave in the same system is independent of the pressure for pressures varying from 1 to 3 atmospheres. It is identical whether the wave be propagated in a tube of caoutchouc or metal, in spite of the different conducting and radiating powers of the two materials. Further, the pressures developed in an explosive mixture detonated at different initial temperatures are sensibly proportional to the density of the mixture, this result being confirmed by experiments with gaseous mixtures that were isomeric in the sense that they gave the same products of combustion while evolving different quantities (the maximum being as much as twice the minimum) of heat.

Less simple laws appear to govern the propagation of the explosive wave in bodies of greater density than that of gases. An experimental study of the subject has been part of the work of the Commission for Explosive Substances, and some of the results have already been published (Annales de Chimie et de Physique, 6, 556). They were obtained by using long tubes (100 m.) of narrow bore, made of lead and tin. The highest velocity (7,700 m. per second) was observed in the case of nitromannite.

The pursuance of this investigation appeared likely to be best undertaken by using a fluid homogeneous explosive substance detonated in tubes of varying resistance but similar mass, and strong enough to resist the explosion. This last condition could not be fulfilled, and as will be seen later there appear to be fundamental reasons why it should be unattainable.

The liquid chosen was methyl nitrate, CH₃NO₃, sp. gr. 1.182. On explosion it may decompose thus:—

or thus—

or both reactions may occur. In either case the volume of the gases produced is the same, viz., 870 litres for 1 kilo. of the original liquid, i.e., 1,028 litres for 1 litre. Its heat of formation is 39.9 large calories, taking the value of carbon as 94.3 cal. The first equation gives a heat of decomposition of 107.7 cal., the second 112.6 cal. at constant pressure, the water produced being assumed to be in the gaseous state. The mean of these values gives 113.1 cal. for 1 kilo. of methyl nitrate. The volume of gas and the heat evolved are similar to the same products of other high explosives. The pressure developed, after allowing for the limit below which the gaseous products of its detonation cannot be compressed, is found to show a similar agreement.

Rate of Detonation.—Experiments were carried out in long tubes placed end to end, the rates being determined by the use of chronographs in the manner previously adopted by the author.

Various materials were used for the tubes.

I. Caoutchouc tubes lined with canvas. Internal diameter 5 mm., external diameter 12 mm. The velocity between the first and second point of observation, 10 m. apart, was 1,616 m. per second. Further on the propagation was irregular, a result ascribable to the rending of the tube.

II. Glass tubes, varying from 3 mm. internal diameter, the walls having a thickness of 4.5 mm. to 5 mm. diameter and 1 mm. thickness. The results varied from 2,482 m. per sec. for the former, to 1,890 m. per sec. for the latter. The rate decreased with the diminution of the thickness of the tube, indicating that it was limited by the more or less immediate fracture of the tube. There was nothing to indicate that the maximum speed was being approached. Even the thinnest glass resisted rupture longer than the canvas-lined rubber, and allowed the attainment of a higher velocity.

III. In Britannia metal tubes 3 mm. in internal diameter and 4.8 mm. thick, the velocity was 1,230 m., the material thus appearing to give way more quickly than either glass or caoutchouc.

IV. Solid-drawn steel tubes 5 m. in length and 3 mm. internal and 15 mm. external diameter, and annealed with the utmost care, were used in the next series of experiments. The velocities observed varied from 2,084 m. to 2,155 m. All the tubes were broken, the fragments generally being in the form of lamellæ, as were those of the rubber tubes, forming a testimony to the homogeneity of the metal and defining the character of its elasticity. The figures lie between those given by caoutchouc and thick glass tubes. They are in all cases lower than those observed with solid explosives, whether dense like compressed gun-cotton or in the form of powder like picric acid.

The failure of the steel tubes makes it more than doubtful whether any material can be found to withstand the explosion. The theoretical reasons are as follows:—

According to the theory of the elasticity of materials, the resistance to rupture of a metal tube does not increase with its thickness indefinitely, but tends towards a limit, and when this is exceeded fracture takes place, whatever be the thickness. But liquid explosives like methyl nitrate present a noticeable peculiarity: Their volume in the liquid state is smaller than the minimum volume below which the gaseous or liquid products of their explosion cannot, as far as we know, be compressed. Taking the explosion of methyl nitrate as a concrete case, we find that the lowest possible volume of its products is about one-fifth greater than that of the liquid before explosion. Consequently the vessel filled with the liquid must be broken before the whole of the explosive has decomposed. The moment of fracture will vary according to the power of the material of the vessel to resist shock; its ultimate static resistance such as is commonly measured by hydraulic pressure, does not here come into play.

Similar considerations applied to other liquid and solid explosives, lead to the conclusions that hydrogen peroxide decomposed into oxygen and water would similarly shatter the vessel containing it, the expansion being 54 per cent., while the figure for fulminate of mercury is 55 per cent. This enormous dilatation, coupled with the great density of the substance and the rapidity of its explosion, explains the shattering action of fulminate of mercury, and the manner in which the products of its explosion, though wholly gaseous, leave marks on the hardest metals, like those made by a cold chisel. Nitrate of ammonia gives a similar expansion amounting to 65 per cent.

It may be here noted that these explosives the formation of which is of course endothermic, suffer a diminution in their synthesis from the products of their explosive decomposition which is in no way inferior to that observed in the case of the best defined exothermic compounds. This result is of importance because it runs counter to most of the conclusions that have been endeavoured to be established concerning the relations between the heat evolved in a reaction and the changes of volume that accompany it.

The author believes that were measurements possible it would be found that the velocity of the explosive wave in liquids is comparable with that of sound in rigid solids, viz., 5,000 m. per second.

A note by Vieille is appended to the paper in which the phenomena already recorded are summarised, and Berthelot's explanation of the method of transmission of the explosive wave in liquids and solids further elaborated. Nitroglycerin exploded in lead tubes having an internal diameter of 3 mm. has given velocities of about 1,300 m. per second, while dynamite, under like circumstances, gave 2,700 m. This higher velocity is due to the influence of the structure of the explosive material on the speed of propagation. Nitroglycerin itself being a viscous liquid transmits the initial impulse more irregularly than when absorbed in siliceous material. Mica dynamite gives still higher results, as might be foreseen on considering its more crystalline structure: nitro-mannite, a solid crystalline body, behaves in a manner consonant with this idea, the velocity given by it being fairly constant and extremely high, viz., 7,700 m. per second. In the same way picric acid evenly crystallised has given 6,500 m. On the other hand, in the case of powdered explosives brought almost into a state of complete continuity by adequate pressure, a limit of compression exists beyond which detonation cannot be effected; this has been observed with certain chlorate mixtures. Further experiments illustrating the influence of the envelope surrounding the explosive in the case of gun-cotton may be quoted.

Compressed gun-cotton with a density of 1 to 1.27 exploded in lead tubes 3.15 mm. in diameter, has given a velocity of 5,400 m. per second; with a density of 0.73 and a tube 3.77 mm. in diameter, the velocity was 3,800 m. per second; the decrease in this case being due to the lower state of compression of the explosive. Gun-cotton in the form of a mere cord with a density of 0.65 gave 2,400 m. per second. But a low resistance on the part of the envelope may be compensated for by the mass of the explosive, the outer parts restraining the instantaneous evolution of gaseous products from the central portion. Abel has observed velocities of 5,300—6,900 m. per second, using cartridges of compressed gun-cotton about 10 times the diameter of the cords above referred to, placed end to end and not enveloped in any way.

The whole investigation has shown that the simple character of a gaseous explosion and the definite nature of the laws which govern it do not obtain in the case of liquids and solids.—B. B.

On Explosives and their Safe Use in Mines. Soupart. Monit. Scient. 37, 114—119.

RECENT experience having shown that most of the explosives in use in mines are dangerous, some owing to the high temperature produced, which is sufficient to ignite the fire-damp, and some to their containing sulphates in large enough quantities to yield on combustion harmful amounts of sulphuretted hydrogen, the following experiments conducted by the inventors under the supervision of the author on a new substance—Favier's explosive—are of considerable importance.

Favier's "antifiredamp" while possessing as much power as dynamite No. 1, is yet perfectly safe in its manipulation; it will not freeze, may be hammered, fired upon at 10 yards, thrown into a fire or touched with a red-hot iron, without exploding.

The following table compiled by the French Commission on Explosives shows the pressure developed on detonating the various substances:—

	Charge.	
	0.2 Grm.	0.3 Grm.
Explosive gelatin	Kilos, 2,081	Kilos, 3,564
Favier's explosive	2,051	3,623
Dynamite No. 1	2,051	2,279

Tried on the author's works by exploding 15 grms. in a hollow block of lead weighing 63 kilos., the capacity of the interior was increased from 140 cc. to 123 cc., "grisoutite" giving only 213 cc.

Further experiments were carried on in an apparatus consisting of a copper vessel of about 10 cbm. capacity, containing a steel mortar to hold the explosive, and fitted with sight holes, leading tubes for filling the vessel with gas, thermometer, a powerful agitator worked from outside

and a steam-coil to enable the explosion to take place at a high temperature. The chamber was filled with a mixture of 100 parts of coal-gas and 12 of air, as being most inflammable, and comparative experiments were tried between dynamite No. 1, "grisoutite," forcite, and Favier's explosive, with and without the addition of coal-dust to the gaseous mixture; the explosions being determined electrically. The results are shown in the table:—

Explosive.	Wad.	Coal-dust.	Temperature.	No. of Experiments.	Results.
Favier's.....	None	Absent	17—24	2	One ignition.
	Clay	Absent	17—18	12	No ignition.
	Clay	Present	16—54	10	No ignition.
	Coal-dust	Present	26—54	10	One ignition at 45.
Grisoutite.....	None	Present	30—37	6	No ignition. No air mixed with gas.
	None	Absent	17—39	10	Seven ignitions.
	Clay	Absent	17—18	3	No ignition.
	Clay	Present	17—53	4	Two ignitions.
Forcite.....	Coal-dust	Present	22—51	10	Seven ignitions.
	None	Present	24—37	5	No ignition. No air employed.
	Clay	Absent	17—46	4	One ignition.
	Clay	Present	18—46	6	Three ignitions.
Dynamite No. 1.....	Coal-dust	Present	44—53	2	Two ignitions.
	None	Present	20—37	6	Six ignitions. No air employed.
	Clay	Absent	37	1	Ignition.

XXIII.—ANALYTICAL CHEMISTRY.

APPARATUS.

The Measurement of Natural Gas with the Pilot Tube-Gauge. S. W. Robinson. *Engineering and Mining J.* 1891, 261—262.

See under H., pages 352—353.

An Error in the Principle of Ordinary Desiccators. W. Hempel. *Ber.* 23, 3566—3568.

THE author draws attention to the fact that moist air being lighter than dry air, the usual practice of placing the drying agent *underneath* the substance to be desiccated and at the bottom of the receiver is open to serious objection, since the action is dependent on the slow mixing by diffusion of the layers of air; of course when the air is highly rarified this is not of so much importance. By placing the drying agent as high as possible and *above* the substance to be dried, the desiccation is rapid and effective owing to a circulation of the air.—O. H.

An Apparatus for Fractional Distillation under Reduced Pressure. H. Schulz. *Ber.* 23, 3568—3570.

THE apparatus shown in the figure, combining simplicity of construction with efficiency and handiness, is specially designed for fractionally distilling large quantities of liquids, particularly for technical purposes. Instead of the more troublesome connexions described by Wislicenus (this *Journal*, 1891, 162), between pump, condenser, and receiver, the simple arrangement shown is employed, in which *k* is the condenser fitting at *e* into the adapter *B* which is drawn

out at *e*, and in which is sealed the tube *d* connecting the interior of the receiver *A* with suction pump. The receiver is connected at *aa* by a piece of rubber tubing with the adapter. Its manipulation is obvious.—O. H.

Automatic Mercury Pump. M. Stahl. Ber. **24**, 147—149.

In this pump, which has been patented in Germany, the mercury is raised by air compressed in a suitable vessel by means of the ordinary water supply, a weight with adjustable slide and the lower mercury reservoir being so arranged on a rocking table that the water supply is automatically cut off, and the water in the air vessel allowed to escape when the mercury has been raised to a predetermined height. The descent of the mercury during the working of the pump reverses the operations.—O. H.

INORGANIC CHEMISTRY.— QUANTITATIVE.

The Application of Electrolysis to Quantitative Analysis. C. A. Kohn.

The Solubility of Gases in Water. L. W. Winkler. Ber. **24**, 89—101.

THE author has commenced a redetermination of the absorption coefficients of gases. He describes minutely the apparatus he employs, and gives results as to the absorption of hydrogen by water.

He finds that the absorption coefficient of hydrogen decreases with rise of temperature as far as 60° C., when it becomes constant. His results agree with those obtained by Timofejew (Zeits. f. phys. Chem. **6**, 141). Bunsen gave the absorption coefficient of hydrogen as constant between 0° and 20° C.

The solubility of oxygen and nitrogen is being investigated. —T. L. B.

A New Method for Analysing Silicates. P. Jannasch. Ber. **24**, 273—278.

THE decomposition of the silicate is effected by means of concentrated hydrochloric acid under pressure. The following apparatus is used:—A tapering platinum tube closed at one end and provided with a specially constructed cap. This cap contains an inner platinum tube, which is soldered to it. The following are the dimensions:—The total length of the platinum tube is 178 mm., the cap being 43 and the tube proper 151 mm. A portion of the cap overlaps the tube to a length of 16 mm. The inner tube measures 32 mm. (23 mm. outside the cap and 9 mm. inside). The diameter of the tube is 15 mm., of the cap 17 mm., and the inner tube 5 mm. The apparatus weighs 57.5 grms. The capacity is 26 cc.

The finely powdered silicate is introduced through the inner tube by means of a funnel, and washed in with 10 cc. of hydrochloric acid containing 4 vols. of hydrochloric acid

to 1 vol. of water. The mineral is well mixed with the acid by the aid of a platinum wire, which is subsequently washed with 5 cc. of acid. The platinum vessel is now introduced into a glass tube, and hydrochloric acid poured into the glass tube until it covers about one-half of the platinum tube. The diameter of the glass tube should be 22 mm. inside and somewhat over 2 mm. thick. When filled the glass tube is drawn out and the air expelled by carbon dioxide, which must be led into the platinum vessel. The tube is sealed and heated from 10 to 12 hours to 190°—210°. The product is washed from the tubes and the acid completely expelled on the water-bath and filtered. The small amount of platinum dissolved from the tube is precipitated with sulphuretted hydrogen. The objections pointed out by the author to this method are the contamination of the solution with platinum chloride and the presence of small quantities of lime and alumina in the silica.

Nothing can be definitely stated as to its general application. The analyses of felspar by this method agree well with results obtained by the ordinary method of fusion with alkali.—J. B. C.

On the Determination of Iron and Alumina in Phosphates. R. Jones. Zeits. f. angew. Chem. 1891, 3—4.

THE author publishes some further improvements on Glaser's method of estimating iron and alumina in phosphates (this Journal, 1890, 111).

Ten grms. of phosphate are dissolved in nitro-hydrochloric acid and the solution made up to 500 cc. 50 cc. (equal to 1 grm. of substance) are evaporated to one-half the volume in a beaker, acidulated while warm with 10 cc. of diluted sulphuric acid (1:5), shaken up, and 150 cc. of alcohol added, shaken up again and allowed to stand for at least three hours. The calcium sulphate is filtered off, washed with alcohol, dried, and weighed. The filtrate is placed in an Erlenmeyer flask, the alcohol distilled off, the residue washed into a beaker, supersaturated with ammonia, and heated till all the ammonia is driven off. The precipitate of ferric phosphate is filtered, washed with boiling water containing ammonium nitrate, without stirring up the precipitate. The filtrate is supersaturated with ammonia, and the magnesia estimated after 12 hours' standing; phosphoric acid, alkalis, and sulphuric acid are estimated in the original solution as usual.

The combination of the methods of Glaser and Stutzer (this Journal, 1890, 218) is only available in the absence of organic matter.—H. A.

Determination of Metallic Aluminium in Commercial Aluminium. F. Regelsberger. Zeits. f. angew. Chem. 1891, 20.

KLEMP's method (this Journal, 1889, 710) of estimating aluminium by means of the hydrogen evolved with caustic potash is incorrect, as the same reaction is obtained with silica, which is a common impurity of commercial aluminium. The author prefers the following method:—Dissolve 2 grms. of the sample in concentrated caustic potash (15 grms. of KOH) in a platinum basin, make up with water to 200 cc., boil 50 cc. of this with ammonium carbonate, filter, wash, and ignite. Deduct from this the alumina of the reagents, which is estimated in the same way.—H. A.

The Precipitation of Manganese as Ammonium Manganous Phosphate. A. G. McKenna. Technology Quarterly, **3**, 333—337.

THE determination of manganese by the usual process of precipitation as dioxide by bromine and subsequent ignition, is subject to two sources of error. First, the precipitate always carries down some of the potassium or sodium salts, whilst if ammonium acetate be employed, the solution must be made alkaline before the precipitation by bromine and the separation from calcium is then rendered less sharp.

Secondly, the composition of the ignited precipitate varies somewhat according to the temperature of ignition and other causes. It is, therefore, now customary to redissolve the manganese dioxide and to reprecipitate it as ammonium manganous phosphate, as proposed by Wolcott Gibbs. The author has examined this method of determination with the object of ascertaining what conditions are essential to accurate results. He finds that no appreciable error is introduced by precipitation and boiling in glass vessels, and that the precipitate is equally insoluble in hot water as in solutions of ammonia or ammonium nitrate. In fact, ammoniacal water dissolves a perceptible quantity of the precipitate when iron is present. The essential condition is that the precipitated ammonium manganous phosphate must be boiled long enough to transform the whole into characteristic silky crystals, which allow of easy filtration, and the time required is about eight minutes boiling with constant stirring to prevent bumping. The washing should be conducted with hot water and the ignited precipitate weighed as manganous pyrophosphate. The results are accurate.—G. H. B.

The Analysis of Ferro-chromium, Ferro-aluminium, Ferro-tungsten, Ferro-silicium and Ferro-titanium. A. Ziegler. *Dingl. Polyt. J.* **279**, 163–166. (See this Journal, 1889, 639, and 1890, 216–218.)

To decompose the above alloys the author uses a mixture of 6 grms. of pure caustic soda or potash, and 3 grms. of pure sodium or potassium nitrate: 0.5 gm. of the powdered and sieved alloy is taken and fused with the flux in a silver crucible. The crucible must have a capacity of about 50 cc. and weigh 15 to 16 grms. The silver crucible is heated in the luminous flame of the Bunsen lamp so that the crucible remains covered with soot.

The author has determined the loss of weight of the crucible after fusion by (1) extracting with water; (2) washing with hydrochloric acid; and (3) cleaning with sand after decomposing ferro-chromium:

	Grm.
L—lost	0.0033
H, and H—lost	0.0072
Total loss	0.0105

The loss after fusion of ferro-aluminium was 0.0138 gm.; ferro-tungsten, 0.0223 gm.; ferro-silicium, 0.0125; and ferro-titanium, 0.0192 grms. Potash salts give similar results.

Ferro-chromium is analysed as follows: 0.5 gm. of powdered alloy is placed in the silver crucible, to which 6 grms. of caustic alkali and 3 grms. of alkaline nitrate are added. The crucible is covered with soot by the reducing flame and gently heated, the temperature being slowly raised. Just before solidification the fused mass is allowed to cover the sides of the crucible and then cooled. The crucible is placed in a porcelain basin and filled up with water.

The solution of the contents may be hastened by stirring with a platinum rod. The solution and precipitate of ferric oxide is transferred to a beaker and saturated with carbon dioxide.

The liquid is evaporated in a basin over the water-bath to dryness, redissolved and filtered. The precipitate is washed with water containing sodium carbonate. The chromium is now completely in solution. The reddish film on the interior of the crucible appears to be silver chromate, and is readily decomposed by dilute hydrochloric acid. This latter solution is added to the iron solution, or the minute quantity of chromium it contains may be determined separately. The chromate solution is made up to a given volume, portions of which are evaporated to dryness with hydrochloric acid, the silica separated and the chromium precipitated twice with ammonia. The insoluble portion of the extract from the crucible contains the iron, manganese, most of the silica, &c. This is dissolved on the filter with hot dilute hydrochloric acid (1 part to 3 parts of water)

and washed with 1 per cent. acid. The acid solution is evaporated to dryness, taken up with dilute hydrochloric acid and filtered. The filtrate contains iron and manganese chloride.

The iron precipitate should be tested for chromium. The silica must be expelled with hydrofluoric acid, and the residue also tested for chromium.

Silicon is best determined by decomposing 0.5 gm. of the substance with sodium bisulphate. The fused mass dissolves in dilute sulphuric acid, leaving the whole of the silica.

The silica is not pure, and must be treated with hydrofluoric acid. In the filtrate from the silica, manganese may be determined. For the determination of phosphorus, 2 grms. are taken and decomposed with 9 grms. of sodium nitrate and 18 grms. of caustic potash. The product is digested with nitric and a little dilute hydrochloric acid, and evaporated repeatedly with concentrated nitric acid. The acid is neutralised with ammonia and phosphorus, determined as usual. The sulphur may be estimated with the same fusion mixture.

The weighed chromic oxide is free from iron or manganese. Any silica present may be found by fusion with sodium bisulphate.

The chromium may also be oxidised with permanganate in sulphuric acid solution to chromate, and titrated with ferrous ammonium sulphate. The author also recommends the oxidation of the sulphuric acid solution of ferro-chromium (after fusion with sodium bisulphate) with permanganate and precipitation of the solution with sodium carbonate, whereby the manganese and iron are completely separated from the chromium. In the determination of ferro-aluminium, the fusion is conducted precisely as in the preceding case, but requires a somewhat longer fusion. During evaporation of the extract no carbon dioxide is used, but a little caustic alkali may be added with advantage. The greater part of the aluminium may be separated from the filtrate without passing in carbon dioxide, by simply neutralising the solution with hydrochloric acid. Another method is to dissolve, in a platinum basin, 0.5 gm. of substance in a sufficient quantity of dilute hydrochloric acid, to evaporate to dryness, and to fuse with excess of sodium carbonate or a mixture of sodium and potassium carbonate. The rest of the process, after separation of the silica, is identical with the chromium method. Or, the dry hydrochloric acid solution may be transferred by the help of a pure filter paper to a silver crucible, and fused with six parts of caustic soda and three parts of sodium nitrate. If the alumina contains iron it may be brought into solution by fusion with sodium bisulphate, and the iron reduced and titrated with permanganate. It appears as if on fusion of the dry acid solution with sodium carbonate, that the ferrous iron passed more readily into the alkaline solution. The author, therefore, recommends the evaporation in a porcelain basin with nitric acid.

Ferro-tungsten may also be decomposed by the same fusion mixture. The product must be evaporated with nitric acid, taken up with warm nitric acid, filtered, and the filtrate tested for tungsten. The residue on the filter is dissolved in ammonia, the insoluble portion fused with sodium nitrate dissolved in water, and the residue in hydrochloric acid, and evaporated repeatedly with nitric acid.

Ferro-silicium may also be treated with caustic alkali and nitrate, but sodium bisulphate in a platinum crucible answers equally well, and the silica may be further tested for purity by treating with hydrofluoric acid and sulphuric acid.

Ferro-titanium is treated as follows:—0.5 gm. of the powdered and sieved alloy is fused with sodium bisulphate as in the decomposition of ferro-chromium, but dissolved in cold water. The silica residue is evaporated with hydrofluoric and sulphuric acid, whereby the silica is determined. Any residue is fused with sodium bisulphate, and is added to the principal solution. This solution is diluted to 1 litre, partly neutralised with ammonia, and sulphur dioxide passed in. The liquid is slowly heated to boiling

and boiled for $1\frac{1}{2}$ to 2 hours. In this first precipitation nearly all the iron remains as ferrous salt. It is filtered through a double filter and washed with 4 per cent. acetic acid. The filtrate must be absolutely clear. It is again partly neutralised with ammonia saturated with sulphur dioxide and boiled again for one hour.

The first precipitate of titanate acid containing iron is burnt, decomposed with sodium bisulphate, and treated as after the first fusion. When properly carried out, the second precipitation yields a pure white precipitate containing only traces of iron. If iron be present, a second precipitation will be necessary.

When titanate acid filters cloudy, dilute ammonium chloride solution may be added or a filter paper in pulp. Titanate acid retains sulphuric acid, and the burnt precipitate must be carefully heated with ammonium carbonate. 0.5 gram. of ferro-titanium is decomposed with aqueous hydrofluoric acid in two hours. Fused sodium nitrate does not take up titanium from ferro-titanium. The alloy treated thus is incompletely decomposed by hydrochloric acid, nitric acid, or aqua regia.

The following notes are added:—

Titanate acid is not soluble in potassium cyanide, potassium sulphocyanide, aluminium nitrate or potassium oxalate. Oxalic acid dissolves titanate acid and basic sulphate of iron completely. Sodium hyposulphite produces a violet colouration in the solution of the fused mass containing titanate acid.—J. B. C.

The Estimation of Aluminium in Iron and Steel. A. Carnot. *Monit. Scient.* **37**, 14–15; and *Compt. Rend.* **111**, 914–916.

THE author's method, which somewhat resembles that of Pattinson and Stead, has been in use in the French School of Mines for eight years, and has been found to give very exact results, while only occupying a few hours.

Ten grms. of the metal are dissolved in hydrochloric acid in a covered platinum basin, and filtered from the insoluble portion; and the filtrate nearly neutralised with ammonia and sodium carbonate. A small quantity of sodium thiosulphate is then added, and when the reduction to the ferrous state is complete, known by the liquid becoming colourless, two or three cc. of a saturated solution of sodium phosphate, and about 20 cc. of sodium acetate (30 per cent.); the liquid is then boiled for about three-quarters of an hour till all smell of sulphur dioxide has disappeared. The precipitate containing sulphur and silica mixed with the aluminium phosphate is filtered off, washed and dissolved in the platinum basin in 10 to 15 cc. of hydrochloric acid diluted with water; the solution is evaporated to dryness and kept at 100° for an hour, redissolved in acid, filtered, diluted with 100 cc. of cold water, and reprecipitated as before.

Experiments by the author on cast iron have given negative results, only traces of aluminium being found, and these being probably due to slag. In cast steel, however, aluminium has been detected in several samples, but whether in the form of an alloy or as alumina is unknown.—F. H. L.

ORGANIC CHEMISTRY.—QUALITATIVE.

Colour Reactions of Aromatic Amines. C. Lauth.

Compt. Rend. **111**, 975–977.

Ox treating dimethylaniline acetate with lead dioxide a deep green colouration is produced (see *Derivatives of Dimethylaniline*, C. Lauth, page 357); this reaction, which is very delicate, causes the production, with most amido-compounds, of characteristic colourations, and may therefore be of use in identifying the same when only small quantities are at disposal. The following is a convenient method of making the test: A drop or small quantity of the amido-base under examination is placed on a watch-glass and mixed with ten drops of dilute acetic acid (3 vols. of acetic acid at 8° B. and 7 vols. of water); generally, the base completely dissolves; should it only partially do so the result is the same; but if the base be quite insoluble in aqueous acetic acid it

is necessary to employ an alcoholic solution of the acid (3 vols. of acetic acid at 8° B. to 7 vols. of alcohol) to dissolve it; in any case it is advisable to make two tests simultaneously, one with aqueous, the other with alcoholic, acetic acid, since the presence of the alcohol, by reason of the aldehyde, &c., formed from it, frequently affects the result. A few grains of lead dioxide are next sprinkled on the edge of the watch-glass, which is then inclined so as to bring the solution of the amido-compound into contact with the lead dioxide, a colouration, as a rule, being instantly visible.

Testing in this way, the author records the following observations:—

COLORATIONS PRODUCED BY THE ACTION OF LEAD DIOXIDE ON AN ACETIC ACID SOLUTION OF THE AMIDO-BASE.

	In presence of Water.	In presence of Alcohol.
Aniline	Red-violet, changing to red-brown.	Same as with water.
Methylaniline	Blue-green, changing to violet, blue, and finally olive.	Violet, red-violet, olive.
Dimethylaniline	Orange, green, green-olive, grey.	Orange, green.
Ethylaniline	Blue-green, blue-violet olive.	Violet, purple, olive.
Diethylaniline	Bright orange, yellow.	Green-yellow.
Benzylaniline	Red-brown, red-violet, grey.	Yellow-grey, green.
Methylbenzylaniline ..	Orange, green-yellow, olive-green.	Bright green, blue-green, violet.
Ethylbenzylaniline ...	Orange.	Olive, bright green, olive.
Diphenylamine	Pale purple-grey.	Bright green, olive.
Methyldiphenylamine ..	Magenta-red, purple, brown.	Purple.
Paratoluidine	Full red, red-brown.	Full red.
Orthotoluidine	Dull green, violet.	Red-violet, purple, dull red.
Dimethylparatoluidine	Olive, yellow-olive.	Olive, yellow-olive.
Dimethylorthotoluidine	Bright orange-red, brown-orange.	Brown olive, olive.
α -Metaxylidine	Blue-violet, grey-black.	Red-violet, dull red.
β -Metaxylidine		
Mixture of α - and β -xylidines.		
Paraphenylenediamine	Bright blue-green, brown.	Bright blue green, brown.
Metaphenylenediamine	Brown.	Brown.
Dimethyl- <i>p</i> -phenylenediamine.	Magenta-red, blue-violet, dark purple.	Magenta-red, blue-violet, dark blue.
Dimethyl- <i>m</i> -phenylenediamine.	Pale brown-yellow.	Yellow-brown.
Tolylene diamine (common).	Bright red-brown.	Bright red-brown.
α -Naphthylamine	Pale blue-violet.	Pale blue-violet.
β -Naphthylamine	Pale yellow-brown.	Pale red-brown.
Dimethyl- α -naphthylamine.	Full red, opaque white.	Madder-red, little soluble.
Benzidine	Deep rich blue, violet, red.	Yellow solution, blue precipitate.
Tetramethylbenzidine	Green-olive (with excess of acid).	Dull green.
Dimethyl- <i>o</i> -anisidine .	Violet-red, dull purple.	Dull green, olive.
Dimethyl- <i>m</i> -anisidine.	Yellow-brown.	Yellow-brown.

Detection of Adulteration of Olive Oil. R. Brullé.Compt. Rend. **111**, 977.

THE test is based on the colourations produced with different oils by a 25 per cent. solution of silver nitrate, and is effected by mixing in a test-tube 5 cc. of the silver nitrate solution with 10 cc. of the sample of oil to be tested, and then heating the mixture on the water-bath for half an hour. Treated in this way:—

(1.) Pure olive oil is coloured green, but remains clear; (2.) arachis oil takes a red-brown tint; (3.) sesamé oil is coloured red; (4.) colza oil becomes first black then dull green; (5.) linseed oil is coloured deep red; (6.) cotton-seed oil is blackened; (7.) poppy oil is coloured dark green; and (8.) camelina oil is rendered very deep red.

—E. B.

New Method for Testing Olive Oils, Seed Oils, Natural and Artificial Butter. R. Brullé. Compt. Rend. **112**, 105—106.

For the discrimination of olive oils and other oils liable to be used for adulteration, the author applies nitrate of silver in the following manner:—25 parts of silver nitrate are dissolved in 1,000 parts of 95 per cent. alcohol, and 5 cc. of this solution are added to about 12 cc. of the oil under examination, which should be filtered if not quite clear, then the test-tube is heated in boiling water, and the effect observed.

Kind of Oil.	Colour after Heating in Boiling Water.
Virgin olive oil,	Bright green.
Olive oil of second and third pressures, containing some olive-kernel oil.	Darkens slightly, quickly changing to intense green.
Olive oil of inferior quality, strongly coloured.	Same as previous oil, but takes longer (15—20 minutes).
Cotton-seed oil, pure,	Black.
Earthnut oil,	Brownish-red, greenish as it loses in transparency.
Sesame oil,	Dark reddish brown, not changing to green.
Rapeseed oil,	Greenish yellow, then opaque.
Poppy-seed oil,	Same as preceding.

The author states that with practice it is possible to determine in many cases thus colorimetrically 5—10 per cent. of one of these oils in a mixture.

In the same way natural butter, which gives no change, may be distinguished from artificial butter, the latter, owing to the presence of margarin, acquiring a brick-red colour; and the proportions in a mixture may be approximately determined.—K. E. M.

ORGANIC CHEMISTRY.—QUANTITATIVE.*The Determination of Impurities in Paraffin Seals, &c.* J. Stuart Thomson.

An Apparatus for Determining the Flash-Points of Heavy Mineral Oils. J. Gray.

See page 348.

On the Adulteration of Mineral Oils with Caoutchouc. Holde. Mitt. Königl. tech. Versuchs., 1890, 308—310.

MINERAL oils are sometimes adulterated with caoutchouc, in order to increase their viscosity and lubricity. For the detection of caoutchouc in mineral oils, it is recommended to:—1. Determine the specific gravity. 2. Ascertain the different degrees of viscosity from 20° to 150° C. 3. Find the quantity of free acids present. 4. Test for fatty oils by saponifying with caustic soda. 5. Test for resin oil by treatment with sulphuric acid of 1.624 sp. gr. (compare this Journal, 1890, 119). 6. Ascertain the solubility by shaking 1 vol. of the oil with 2 vols. of alcohol, benzene, or ether. 7. Precipitate the caoutchouc contained in the oil

by treating the latter with a mixture of 3 parts of ether and 4 parts of alcohol. The precipitate is weighed, after having been filtered, washed and dried.—H. S.

Mineral Lubricating Oils used in Italy. V. Villavecchia and G. Fabris. Report of the Central Laboratory of the Italian Customs Department, 1891.

THE duty upon heavy mineral oils being 6 and 12 lire per quintal, according as they contain under 20 per cent. or from 20—30 per cent. of light oils respectively, whilst the duty upon illuminating oils is 47 lire per quintal, a class of heavy oils containing about 20 per cent. of light oils has recently been largely imported into Italy for purposes of adulteration. As it is proposed to change the tariff so as to exclude these mixtures, the experiments described in the report were undertaken in order to discriminate between them and genuine lubricating oils.

In these experiments the acidity was determined by Martens' method (this Journal, 1890, 902, 1042); the colour by Stammer's colorimeter; the specific gravity with Greiner's densimeter; the viscosity with Engler's viscosimeter (this Journal, 1890, 654); the solidifying point by agitating the oil in a small thin glass cylinder placed in a vessel containing alcohol cooled to -15° , and observing the change produced by the gradual fall of temperature; the flashing point by heating the oil in a crucible and arranging a small flame about 7 or 8 mm. above the surface of the oil; the percentage of light oils by distillation in a flask, resembling Engler's, but with a shorter stem and larger bulb (this Journal, 1890, 1074); vegetable oils and fats were looked for by Lux's method (this Journal, 1885, 746). The following observations are of general interest. Dark coloured and bituminous oils containing an admixture of vegetable oil, fat, &c., do not solidify when heated with solid caustic potash to 200—210°, but acrolein is evolved. In the use of Greiner's densimeter it is of the greatest importance to keep the temperature constant, the correction tables provided not being equally applicable to all classes of oils. The viscosity apparatus must be made perfectly clean before each experiment, the efflux aperture being especially attended to; in two consecutive experiments with the same oil made without disturbing the apparatus, equal quantities of oil flowed out in 1,898 and in 1,471 seconds respectively. The authors' results show that not only does the viscosity diminish very rapidly with a rising temperature, but that the decrease is relatively greater in the more viscous oils. The following are some of the figures obtained:—

SPECIFIC VISCOSITIES (WITH RESPECT TO WATER).

	No. 1.	No. 2.	No. 3.	No. 4.	No. 5.	No. 6.	No. 7.
At 20°	41.39	51.07	40.85	38.77	72.03	67.92	56.03
At 50°	6.81	5.94	5.50	6.03	8.35	9.66	5.71

In technical analyses it is therefore important to determine the viscosity at the temperature which the oil would have whilst in actual use. An addition of light oil to heavy oils greatly reduces their viscosity, more especially of those which have a high viscosity at ordinary temperatures.

From an analysis of the experiments with 85 samples of heavy mineral oils and a comparison with the results obtained by Martens (this Journal, 1890, 902, 1042), and Knukler (this Journal, 1890, 197, 198), the authors conclude that besides the varieties of oil already described, a heavy oil is imported into Italy of a clear yellowish, or at most, reddish-yellow colour, with a specific gravity equal to or less than 0.870, and a viscosity at 20° of about 22 (colza oil 100), characters which would render it a valuable adulterant for illuminating oils.—S. B. A. A.

The Analysis of Spirits. E. Mohler. Compt. Rend. **112**, 53—55.

THE method described is general in its scope, and allows of the determination of the alcohol, extract, acidity, furfural, ethers, aldehydes, higher alcohols, and nitrogenous bodies

in the alcohols and spirits of commerce, on as small a quantity as 500 cc. The determinations needing notice are those of the ethers, aldehydes, higher alcohols, and nitrogenous bodies, and are, with exception of the last, made on the liquid obtained by distillation and brought to a strength of 50°.

Ethers.—100 cc. is boiled with 20 cc. of decinormal potash for one hour under a vertical condenser; the potash absorbed by saponifying the ethers is ascertained by titration, and after allowing for the acidity of the spirit is calculated to ethyl acetate.

Aldehydes.—10 cc. of a solution containing $\frac{1}{100000}$ of aldehyde and 10 cc. of the spirit to be tested, both at 50° strength, are treated with 4 cc. of rosaniline bisulphite; the tests are compared after 20 minutes in a Dubose colorimeter; as the colouration is not proportional to the quantity of aldehyde, the alcohol being examined has to be diluted and the comparison repeated until identity is attained.

Higher Alcohols.—100 cc. of the distilled sample is heated with 1 cc. of aniline and 1 cc. of phosphoric acid for one hour under a vertical condenser, and then distilled to dryness in a salt-bath. The distillate thus freed from aldehydes is treated with sulphuric acid at 66° B. in the usual way, and the tint compared with that given by an alcoholic solution of iso-butyl alcohol containing 0.25 grm. per litre in the same manner as was described in the case of the aldehydes.

Nitrogenous Bodies.—100 cc. of the original sample (not distilled) is distilled with 2 cc. of phosphoric acid at 45° B. The residue containing the phosphates of the bases is diluted with about 1 litre of distilled water, 10 grms. of sodium carbonate added, and the mixture distilled until the distillate gives no colouration with Nessler's reagent. Alkaline permanganate is then added, the distillation proceeded with, and the ammonia estimated as before. The first portion corresponds to the amides and saline ammonia, the second to the pyridine bases and alkaloids.

A lengthy table is appended to the paper showing the results obtained by these methods for natural and factitious spirits. In general the total amount of matter other than alcohol and extract in the latter is only about one-third to one-sixth that of the quantity in the former. The author hopes when a sufficient number of analyses have been accumulated to be able to determine the limit below which a spirit may be considered adulterated.—B. B.

New Books.

CHEMISTRY IN SPACE. From Professor J. H. Van 't Hoff's "Dix Années dans l'Histoire d'une Théorie." Translated and edited by J. E. MARSH, B.A., Demonstrator in Organic Chemistry at the University Laboratory, Oxford. Oxford: At the Clarendon Press. 1891. London: Oxford University Press Warehouse, Amen Corner, E.C.

OCTAVO volume bound in cloth. Price 4s. 6d. It contains Preface, Table of Contents, and text covering 124 pages, one sheet of Diagrams, and Alphabetical Index. The subject-matter is sub-divided as follows:—Historical. The Asymmetric Carbon Atom. The Single Linking of Carbon. Separation of Compounds inactive by Compensation. Point of Transition. The Unsaturated Compounds of Carbon. Further Development of the Theory. Conclusion.

Trade Report.

TARIFF CHANGES AND CUSTOMS REGULATIONS.

PHILIPPINE ISLANDS.

New Customs Tariff.

The following is a statement of some of the rates of Customs duty now levied in the Philippine Islands on articles imported from abroad under the new tariff which came into operation on the 1st April.

Note.—Kilogramme = 2.204 lb. avoirdupois. Peso = 4s. 2d. (nominal value). Hectogramme = 3.215 oz. troy.

No. in Tariff.	Classification of Articles.	Rates of Duty.
CLASS I.—STONES, EARTHS, MINERALS, GLASS, AND CERAMIC PRODUCTS.		Pes. Cts.
<i>Schist, Bitumen, and their Derivations.</i>		
6	Tar, pitch, asphalt, bitumen, and schist ..	100 kilos. 0'09
7	Naphtha oils, vaselin, crude, natural petroleum, and crude oils derived from schist.	" 2'00
8	Benzene, gasoline, and petroleum, and other mineral oils, refined.	" 3'00
<i>Minerals.</i>		
9	Mineral oils	1,000 kilos. 0'25
<i>Crystal and Glass.</i>		
10	Blown glass, common and ordinary	100 kilos. 1'60
11	Crystal, and glass imitation of the same, also gilt and plated in the interior.	" 6'00
12	Plate and sheet glass	" 3'00
13	Silvered glass and crystal and glasses for telescopes and watches.	Kilog. 0'05
<i>Earthenware and Porcelain.</i>		
14	Tiles, bricks, and plaques for building purposes, and crucibles.	100 kilos. 0'02
15	Glazed bricks and tiles, and earthenware pipes, glazed tiles, glazed bricks, and pipes.	" 0'40
16	Stoneware and fine earthenware	" 6'00
17	Porcelain	" 10'00
CLASS III.—SUBSTANCES USED IN PHARMACY, PERFUMERY, AND THE CHEMICAL INDUSTRIES.		
58	Coco and palm oil and other heavy oils ..	" 0'20
59	Vegetable oils of other kinds except olive oil.	" 4'00
60	Woods and barks for dyeing and tanning.	" 0'02
61	Madder	" 4'00
62	Sesame, linseed, and other oleaginous seeds, including copra.	" 0'04
63	Other vegetable products not elsewhere specified.	" 2'00
64	Animal products used in medicine	" 0'60
<i>Colours, Dyes, and Varnishes.</i>		
65	Ochres and other earthy colouring matter.	" 0'02
66	Indigo and cochineal	" 2'00
67	Extracts for use in dyeing	" 0'60
68	Extract of madder	Kilog. 6'15

EXTRACTS FROM DIPLOMATIC AND CONSULAR REPORTS.

PROPOSED SUGAR LEGISLATION IN FRANCE.

The Earl of Lytton, Her Majesty's Ambassador at Paris, in a despatch to the Foreign Office, dated the 25th February, encloses a copy of the report drawn up by the Budget Committee appointed to examine the Bill on sugar duties recently presented to the Chamber of Deputies. This Bill provides as follows:

After the 1st September next, and for subsequent seasons, the legal yield per 100 kilos. of beets worked in native sugar factories is fixed at 7.75 kilos.

When the real yield of each factory does not exceed 10.5 kilos. of refined sugar per 100 kilos. of beet, the excess is admitted to the benefits of the reduced duty provided by the first paragraph of the first article of the law of the 5th August 1890.

Half of the excess obtained over 10.5 kilos. of sugar per 100 kilos. of beets only equally benefits by this reduced duty; the other half is added to the charge leviable with the full duty of 60 francs per 100 kilos.

To those manufacturers who, before the 15th October in each year, declare to the Excise Bureau that they elect to give up the bounty on the excess yield, a waste of 15 per cent. will be allowed on the total amount of their manufacture.

Sugars corresponding to this waste are liable to a duty equal to that which is applicable to sugars representing excesses.

The waste in manufacture allowed to distilling manufacturers by Article 6 of the law of the 5th August 1890 is reduced to 15 per cent., dating from the 1891—92 season.

For the 1890—91 season a waste of 15 per cent. on the total amount of their manufacture will be allowed to the manufacturers of sugar who, by a declaration made at the excise office within five days after the promulgation of the present law will give up the bounty on sugars obtained over and above the legal yield (*prise en charge*).

THE LAURIUM MINES IN 1890.

Mr. H. Lewis Dupuis, Her Majesty's Consul at the Piræus, in a report to the Foreign Office dated the 26th February, quotes the following details of the operations of the Laurium mines in 1890 from the report of Vice-Consul Desposito:—

The Greek company which began by smelting the ancient scorie 15 years ago, having nearly used up that of the old works, obtained the concession of all ancient mine refuse on mineral grounds, known as bevolades, which spread over a surface of about 300 acres. These, it is estimated, contain about 4 to 9 per cent. of lead, and 75 to 200 grms. of silver per ton of ore. The dressing of the ore, as it is called, is done by complicated machinery which washes it and extracts from 7 up to 15 per cent. of lead, and 1,700 to 1,800 grms. of silver per ton of lead. The plant alone for these operations occupies a space of about 10,000 metres, and similar works are now in course of construction to work over the mud and refuse left by the first by a new and improved system of machinery, for which an outlay of 2,400,000 frs. was sanctioned for the building and machinery. The section now at work gives employment to about 1,200 workmen, and turns out sufficient dressed ore to feed 13 furnaces (Pitz's system).

The raw material or mineral earth dressed during last year amounted to 246,000 tons; this was supplied from different sources within the limits of the concession. Original contents of lead averaged 4.05 per cent. with 75 grms. of silver, and produced 68,800 tons of dressed ore containing 10.87 per cent. lead and 1,910 grms. of silver to the ton of lead. The best part of the large deposits of mud and sand left by the washing is shaped into bricks and smelted with other raw material, but this will soon be discontinued, and the work will be passed on to the new section when ready, which will enrich them from 3, the actual contents, to 20 per cent. lead. Herr Lury, the inventor and patentee of the machinery, undertakes to realise such a result, from essays and trials made in his factory at Dresden. The quantity of these new washing refuses of mud and sand, which has to be re-worked by Herr Lury's system, is calculated to amount to about 2,500,000 tons. This will keep the company going for some 10 or 12 years longer on this alone, after which there will still remain the large quantity of non-worked bevolades which have to undergo the first and second dressing. The company, however, in order to secure a long life to their enterprise, work two mines in the district and one in Asia Minor; the output of the three will keep their furnaces supplied with a quantity of virgin lead ore, and galena, which is now being mixed up with dressed ores.

During 1890 the company's 13 furnaces smelted 99,518 tons of dressed and undressed ore, which yielded 8,081 tons of lead containing about 1,694 grms. of silver per ton, at a cost of 1,892,522 dr., the market value of which was about 110,000l. The import of galena (55 to 60 per cent.) from the concession in Asia Minor, included in the above quantity of smelted ore, was 1,076 tons, this added to 68,800 tons dressed ore, and 1,399 tons of iron lead ore, and 13,643 tons of sulphuric lead ore, obtained from their mines at Laurium, make up the 99,518 tons which fed the furnaces during 1890.

7,531 tons of lead were shipped to the United Kingdom, and 550 tons to Italy. The same company erected, two years ago, works for the disargeneration of part of their lead, but though good from an industrial point of view, the result commercially cannot be said to be a profitable one. The

diligently being to find a market for the sweet lead and silver produced at a price proportioned to the heavy expenses entailed by the works, they were therefore obliged to carry it on on a very small scale, and the quantity of pig lead submitted to disargeneration was only 567 tons, which produced 481 tons of purified sweet lead and 340 kilos. of silver. The lead was sold in Athens and Syra, but the silver had to be sent to England. The number of hands employed by this company in all the various branches of their works amounts to 3,500 all told. This company owns the Attica railway, connecting Laurium and the surrounding villages with Athens. The capital engaged for this was 5,500,000 dr., and last year's balance sheet shows a net profit of 181,390 dr.

The French company was started in 1875, with a capital of 16,000,000 frs.; head offices being in Paris, with a representative at Athens. The mining and smelting operations carried on by them are very extensive and important, and the results are better than those of the Greek company, owing to superior management. The mines owned by this company, including the concessions obtained during the last 15 years, extend over an area of about 11,300 acres, and the underground works hitherto executed may be estimated at upwards of 5 kiloms. The centre of these works is at Camarisa, where several ancient pits having been explored, now reach a depth of about 500 feet, divided into three storeys, and connected by an underground railway. These mines, besides lead ore and galena, produce several kinds of zinc ore. Five miles from the mines are the buildings, dressing machinery, lead smelting and zinc calcinating furnaces, and the employes' and workmen's dwellings, a village in itself, half a mile from Ergasteria, and it is there that the working of the different ores is carried on.

The produce of these mines during 1890 was as follows: raw zinc ore (eakmine), 55,704 tons, containing about 27 per cent. and 458 tons of lead ore. This ore was first tested, and the poorest dressed by washing; the whole afterwards was calcinated, and produced marketable stuff of about 31,089 tons, containing about 50 per cent. of zinc, value 186,530l.—(No. 834, *Foreign Office Annual Series*.)

PHOSPHATE LANDS IN FLORIDA.

Writing with regard to a recent discovery of phosphate lands in Florida, Mr. A. de G. Fonblanque, Her Majesty's Consul at New Orleans, in his last annual report to the Foreign Office, says:—

A short time ago quite an important discovery was made in Florida, which is not only contributing to the wealth of certain portions of the State, but is opening up a large export demand. I refer to the discovery of phosphate lands in Florida. The *Times Union Trade Report* for 1890 says: "To tell one half of the wonderful phosphate story of Florida would require several pages of the trade edition. As it goes to press the whole State of Florida is stirred from centre to circumference over the wealth which this discovery promises. The business is not only in its infancy, it may be said to have hardly been born as yet. To present anything like an exhaustive review of it at present would be impossible."

To give some particulars about this interesting discovery it may be related that about the middle of the year 1888 a gentleman, while digging a well in his yard at Ocala, Florida, found marly earth, which was examined and found to be a chalky lime substance not unusual in that portion of the State. It was, however, determined to have the "stuff" properly analysed, and a parcel of it was sent to eminent chemists of a large western city for analysis. The reports were that the stuff was rich in phosphoric acid, and advised that if there was much of it to look after it, as it was valuable. Other similar scientific establishments in large cities confirmed these reports, whereupon the land from which the sample was taken was searched, and the marly substance was found there in quantities, and also at several other places on adjoining properties. About 8,000 acres of these phosphate lands were immediately purchased in the "phosphate belt" followed by other purchases. A company was soon organised, which secured early in the year about 15,000 acres of choice phosphate lands. Other companies

have since been formed which have also secured extensive quantities. I have heard of several vessels loading at some of the ports in Florida nearer to the phosphate beds, and among them some British steamers.

A house is, I am informed, about to be established at Pensacola by parties from the northern States of this country (and who are operators in fertilisers in Ireland for shipment abroad) for the purpose of putting up a regular factory there for the preparation of the crude phosphate into superphosphate, or whatever the refined article may be termed—for general fertilising purposes. This phosphate business will, I am informed, add immensely to the circulation of money in Florida, and, of course, thereby be of general good to large portions of the State. The working population, it is supposed, will also materially benefit in the work of excavation, &c. that must go on in connexion with the business. The original proprietors, or pioneers, in this new industry will also get rich, no doubt, in addition to the actual possessors of the phosphate land.—(No. 833, *Foreign Office Annual Series*.)

GENERAL TRADE NOTES.

THE DEVELOPMENT OF THE RUSSIAN MATCH INDUSTRY.

The February number of the *Deutsches Handels Archiv* devotes an article to this subject, from which it appears that the industry has developed to such an extent within the last four years that Russia is being gradually enabled to cover her own requirements by manufacture. In 1881 the quantity of matches imported across the European frontier of Russia was 39,000 pounds, but from that time there has been a steady decrease in these imports, and in recent years they have become quite insignificant, for instance, in 1884 the total imports were 42,667 pounds, and for each succeeding year they were as follows:—31,007 pounds, 20,216 pounds, 8,786 pounds, 1,827 pounds, and in 1889, 572 pounds (the pound = 36 lbs. avoirdupois).

In 1889 there were 864 pounds of matches exported from Russia. During the same year there were 312 match factories at work, which produced 139,704 millions of matches. It is not possible to give comparative figures for 1888, as reliable returns have only been compiled since May of that year, that is, since the introduction of the match tax. The production for the period from May to the end of the year 1888 was 59,355 millions of matches, and there can be no doubt that the production of 1889 greatly exceeded that of the previous year. The average production per factory during eight months of 1888 was 213.5 million, and that for 1889, 447.8 million, although there were 34 more factories at work in the latter year.

Of the factories at work during 1889, 77 per cent. manufactured phosphorus matches, 5.4 per cent. produced an article free from phosphorus, and 17.6 produced both kinds. The match tax yielded a revenue in 1889 of 4,222,795 roubles, exceeding the budget estimate by 3,029,000 roubles, or 46 per cent.

TALLOW TRADE OF RUSSIA.

The following is an extract from a recent report of the Belgian Consul-General at Moscow:

The principal houses of Northern and Central Russia engaged in the tallow export trade are at St. Petersburg. This capital serves as an outlet for tallow coming from the distant regions in the Empire, notably the governments of Siberia, Perm, Kazan, Samara, Orenburg, Smolow, &c. There are estimated to be in Russia nearly 100 works, which annually produce 2,000,000 pounds of tallow. The most important works are situated in the following governments:—Orenburg, Samara, Perm, St. Petersburg, Ekaterinoslaw, Tambow, Cherson, and Moscow.

The exportation is relatively small, the major part of the production of tallow being consumed by the candle and soap factories. Among these establishments may be mentioned the factory of Krestofnikow Brothers, at Kazan, which annually uses more than 600,000 pounds of tallow of

native origin, and the Noya Company, whose factories at Moscow and St. Petersburg consume almost as large a quantity of native tallow, and more than 150,000 pounds of tallow imported from abroad.

The exports amount, according to official data, to 186,958 pounds, distributed as follows:—

By the Baltic Sea frontier, 65,857 pounds; Russo-Prussian frontier, 8,352 pounds; Black Sea frontier, 48,553 pounds; Sea of Azov frontier, 63,569 pounds; Russo-Austrian frontier, 627 pounds.

By the principal ports:—Taganrog, 63,530 pounds; Odessa, 46,220 pounds; St. Petersburg, 40,976 pounds; Libau, 10,932 pounds; Revel, 7,359 pounds; Port Baltic, 3,154 pounds; Riga, 3,434 pounds.

The principal countries of destination are:—Turkey, 107,419 pounds; Germany, 41,706 pounds; England, 16,258 pounds; Netherlands, 15,846 pounds; France, 3,597 pounds.

Up to the 1st August 1890 the exports had not exceeded 100,000 pounds.

PRODUCTION OF BAUXITE IN ARKANSAS.

Bradstreet's for the 7th March has the following:—

It has recently been reported to the Government that extensive deposits of bauxite exist in Arkansas in irregular patches. As this mineral has only hitherto been found in small quantities, and, with the exception of a single bed in Georgia, never before in the United States, "the find is likely to prove a valuable one." The growing demand for the better class of refractory crucibles and tiles has caused an increased use of this mineral; and as it is also employed in some of the aluminium processes and for the manufacture of alum and aluminate of soda, the discovery is of great commercial interest.

OIL PRODUCTION OF NEW ZEALAND.

The following notes with regard to the oil production of New Zealand are taken from the report of the Registrar-General for that colony for the year 1889:—

Petroleum Oils.

Some very fine oils have been found in the colony. In reference to this, Sir James Hector remarks: "There are three principal localities, and these produce each a distinct kind of oil: the Sugar loaves, in the Taranaki province; Poverty Bay, on the east coast of the province of Auckland; and Manutahi, Waipatu, East Cape. The oil from the first has a very high specific gravity, 0.960 to 0.964 at 60° F. (water 1). It has thus too much carbon in its composition for its commercial success as an illuminating oil, but is capable of producing a valuable lubricating oil. The second kind, from Waipatu, Poverty Bay, is a true paraffin oil resembling the Canadian oil. The third produces a pale brown oil, nearly or quite transparent, specific gravity 0.829 at 60° F., which burns well in a kerosene lamp for some time, and is therefore of a very superior class. It contains only traces of paraffin, and produces 84 per cent. of an illuminating oil fit for use in kerosene lamps by means of a single distillation." Specimens of oil shales have been found at Kaikora and Blueskin in Otago; and at Orepuki, in Southland, extensive and apparently valuable formations of shale have been discovered. Attempts have been made to develop the oil resources at Waipatu, but marketable petroleum cannot yet be classed among the industrial products of the colony.

PAPERS OF INTEREST TO TECHNOLOGISTS AND MANUFACTURERS.

The following articles in the *Board of Trade Journal* for April will repay perusal:—

"Trade Mark Laws of America," p. 379.

"Sugar Production in Central and South America," p. 384.

"Production of Caoutchouc in Brazil and Mexico," p. 390.

"The Ramie Industry in Mexico," p. 447.

"Natural Products of the Amazon Valley," p. 449.

INFLAMMABLE LIQUIDS BILL.

193. FEBRUARY 9TH, 1891.

A Bill to amend and consolidate the law relating to the keeping, selling, and conveyance of inflammable liquids.

The term inflammable liquid is held to include carbon bisulphide and all varieties of liquid petroleum or oil prepared from coal, shale, &c., except liquids having a specific gravity above 1,000 or of specific gravity above 846 and flashing point above 150° F. Any such liquid having flashing point below 73° F. is termed a *mineral spirit*, above 73° F. a *mineral oil*. The Bill provides for the licensing and registration of all places used for the storage of inflammable liquids. The quantity allowed to be stored is regulated according to the means employed in storage, whether wholly or partly in tanks, and whether underground or not. The quantity allowed to be stored also depends on the distance from "protected" buildings, as theatres, churches, &c. Receptacles of inflammable liquids are to be marked in a distinctive manner as, *e.g.*, by a coating of yellow paint. Places of storage may be entered and inspected by the proper authorities at all times. A sample of any liquid suspected to be an inflammable liquid may be taken by the police for the purpose of testing, the regulations with regard to the taking of samples being similar to those of the Food and Drugs Act. Hawkers vending inflammable liquids may not carry any article likely to cause the inflammation of an inflammable liquid. The regulations for conveyance do not call for special remark; they are to be supplemented by byelaws of the railway companies, &c. to be approved by the Secretary of State. In case of accidents arising from the inflammation of inflammable liquids special inquiries may be instituted by the Secretary of State in which specialist and other witnesses may be examined as in other such inquiries.

Acts Repealed.—Petroleum Acts of 1871 and 1879, Hawker's (Petroleum) Act of 1881.—V. C.

SUMMARY OF EXPORTS.

	Month ending 31st March	
	1890.	1891.
	£	£
Metals (other than machinery)	3,193,151	3,780,663
Chemicals and medicines	711,152	846,273
Miscellaneous articles.....	2,800,032	2,954,560
Total value of all exports.....	20,067,022	21,663,378

IMPORTS OF METALS FOR MONTH ENDING 31ST MARCH.

Articles.	Quantities.		Values.	
	1890.	1891.	1890.	1891.
Copper:—			£	£
Ore..... Tons	12,507	6,226	113,943	57,673
Regulus	6,103	6,373	186,168	198,286
Unwrought	5,631	3,169	184,504	170,125
Iron:—				
Ore.....	426,382	257,884	356,121	230,232
Rolt, bar, &c.	1,076	3,126	38,852	33,079
Steel, unwrought..	536	553	6,469	6,757
Lead, pig and sheet ..	13,245	10,536	172,428	133,767
Pyrites	63,248	51,811	112,147	98,766
Quicksilver..... Lb.	26,250	822,556	3,194	92,305
Tin	51,330	65,183	250,085	296,572
Zinc	3,925	1,924	88,266	114,768
Other articles ...Value £	117,351	398,823
Total value of metals	1,929,528	1,831,153

IMPORTS OF RAW MATERIALS FOR NON-TEXTILE INDUSTRIES FOR MONTH ENDING 31ST MARCH.

Articles.	Quantities.		Values.	
	1890.	1891.	1890.	1891.
Bark, Peruvian .. Cwt.	12,670	16,329	£	£
Bristles..... Lb.	291,052	275,796	49,336	38,771
Caoutchouc..... Cwt.	27,720	22,245	29,190	43,265
Gum:—				
Arabic.....	1,058	5,506	338,916	286,843
Lac, &c.....	12,839	13,879	13,296	15,568
Gutta-percha	5,240	5,831	49,079	54,889
Hides, raw:—			70,753	83,429
Dry.....	18,703	47,097	127,916	119,032
Wet	51,780	38,221	118,493	83,268
Ivory	922	1,057	46,429	53,262
Manures:—				
Guano	3,630	1,871	20,502	10,492
Bones.....	6,750	7,903	35,661	47,602
Paraffin..... Cwt.	51,639	51,651	65,258	76,743
Linen rags..... Tons	3,231	2,656	33,534	24,783
Esparto.....	16,945	19,383	82,079	95,805
Pulp of wood	9,500	10,044	56,111	59,565
Rosin..... Cwt.	167,223	137,343	35,674	30,596
Tallow and stearin ..	144,929	135,269	179,691	172,633
Tar	7,469	2,027	1,729	1,069
Wood:—				
Hewn	136,810	138,927	352,886	227,834
Sawn	81,232	92,837	219,104	216,155
Staves	5,599	3,724	35,796	22,276
Mahogany	5,455	3,837	51,154	37,709
Other articles....Value £	690,871	789,807
Total value	2,695,441	2,591,726

Besides the above, drugs to the value of 66,093£, were imported, as against 74,967£ in March 1890.

IMPORTS OF CHEMICALS AND DYE-STUFFS FOR MONTH
ENDING 31ST MARCH.

Articles.	Quantities.		Values.	
	1890.	1891.	1890. £	1891. £
Alkali..... Cwt.	1,949	6,746	1,946	3,818
Bark (tanners, &c.) ..	39,327	31,160	16,647	9,549
Brimstone	42,578	38,754	9,536	11,517
Chemicals..... Value £	110,325	112,716
Cochineal	500	266	3,012	1,592
Cutch and gambier Tons	1,390	1,373	37,257	33,378
Dyes:—				
Aniline	21,985	21,317
Alizarine	29,598	32,780
Other	774	1,196
Indigo	19,167	7,499	348,634	150,622
Madder	1,187	771	1,512	1,041
Nitrate of soda....	639,672	241,635	29,674	96,591
Nitrate of potash ..	32,017	32,371	28,260	28,858
Valonia	2,783	1,513	55,326	31,617
Other articles... Value £	187,903	162,233
Total value of chemicals	1,121,969	706,745

IMPORTS OF OILS FOR MONTH ENDING 31ST MARCH.

Articles.	Quantities.		Values.	
	1890.	1891.	1890. £	1891. £
Cocoa-nut..... Cwt.	16,799	1,985	25,009	2,850
Olive	2,568	1,529	97,351	62,084
Palm	72,069	59,955	74,774	59,352
Petroleum	6,662,239	10,993,410	173,178	239,854
Seed	1,389	2,594	49,876	65,160
Train, &c..... Tons	820	745	17,974	15,668
Turpentine	23,969	15,047	96,963	21,344
Other articles .. Value £	73,178	76,368
Total value of oils...	538,809	534,674

EXPORTS OF DRUGS AND CHEMICALS FOR MONTH ENDING
31ST MARCH.

Articles.	Quantities.		Values.	
	1890.	1891.	1890. £	1891. £
Alkali..... Cwt.	417,269	542,988	128,402	206,126
Bleaching materials ..	100,129	111,552	29,417	38,446
Chemical manures. Tons	28,211	35,156	189,807	252,771
Medicines..... Value £	39,170	91,670
Other articles	270,986	278,860
Total value	711,152	843,273

EXPORTS OF METALS (OTHER THAN MACHINERY) FOR
MONTH ENDING 31ST MARCH.

Articles.	Quantities.		Values.	
	1890.	1891.	1890. £	1891. £
Brass..... Cwt.	7,429	8,748	36,620	49,077
Copper:—				
Unwrought	62,247	84,365	166,217	249,023
Wrought..... ..	24,125	24,136	65,852	89,509
Mixed metal....	17,892	25,851	51,725	72,121
Hardware	231,231	215,793
Implements.....	107,278	110,537
Iron and steel.... Tons	324,721	255,439	2,545,610	2,105,729
Lead	4,979	3,517	62,859	51,873
Plated wares... Value £	37,904	26,834
Telegraph wires, &c.	51,390	892,552
Tin	7,976	8,212	37,970	38,913
Zinc	12,397	12,969	11,841	13,744
Other articles .. Value £	15,624	96,908
Total value	3,493,151	3,780,693

EXPORTS OF MISCELLANEOUS ARTICLES FOR MONTH
ENDING 31ST MARCH.

Articles.	Quantities.		Values.	
	1890.	1891.	1890. £	1891. £
Gunpowder..... Lb.	918,600	750,800	25,435	17,916
Military stores.. Value £	106,505	63,927
Candl'rs..... Lb.	1,256,800	1,428,800	23,916	28,132
Caoutchouc	94,297	103,116
Cement..... Tons	57,655	65,641	117,603	131,245
Products of coal Value £	133,351	174,218
Farthenware	130,641	165,311
Stoneware	17,659	18,002
Glass:—				
Plate..... Sq. Ft.	256,550	267,032	12,642	17,730
Flint..... Cwt.	12,337	8,435	23,123	20,167
Bottles..... ..	75,276	67,184	35,911	31,514
Other kinds.... ..	13,674	19,489	11,063	16,713
Leather:—				
Unwrought	12,734	14,306	115,482	129,131
Wrought	29,367	32,979
Seed oil..... Tons	5,673	7,968	125,085	167,369
Floorcloth	1,698,900	1,731,700	7,984	79,179
Painters' materials Val. £	132,879	136,330
Paper	85,313	89,284	147,389	154,973
Rags..... Tons	3,427	3,754	56,470	25,764
Soap..... Cwt.	49,186	49,231	45,792	51,742
Total value	2,899,632	2,951,600

Monthly Patent List.

* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

4870. R. K. Boyle. Improvements in apparatus for compressing air or gases. March 18.

4972. J. A. Fletcher, S. Fletcher, and J. Fletcher. Improvements in furnaces for melting metals in crucibles. March 20.

5175. S. C. Hauberg. Improvements in centrifugal apparatus for testing the composition of milk and other compound of fluids. Complete Specification. March 23.

5340. A. Dervaux. An improved mode of and apparatus for clarifying muddy liquids. March 25.

5342. H. L. Callendar. Improvements in electrical thermometers or pyrometers. March 25.

5442. M. Gehre. An improved process of and apparatus for ascertaining the percentage of liquid contained in steam or vapour. March 28.

5510. R. Gough. A new or improved apparatus and means for the aëration of carbon in filters. March 31.

5529. J. S. Sawrey and H. Collet. Improvements in apparatus for separating liquids from solid matter suspended therein. March 31.

5555. R. Haddan.—From J. W. Evans, United States. Improvements in evaporators. Complete Specification. March 31.

5749. J. Johnson.—From T. S. Blair, jun., United States. Improvements in refractory linings for furnaces. April 3.

5919. H. J. E. Jensen. Improvements in apparatus for purifying water and for lixiviating chemicals. April 6.

5924. O. M. Row and J. B. Brew. Improvements in apparatus for heating or evaporating liquids. April 7.

5931. J. J. Hardy and W. H. Hardy. Improvements in valve seats, and in the general construction of acid-resisting valves and cocks. April 7.

6057. W. H. Munns.—From G. Kaffenberger, United States. Improvements in digesting apparatus. April 8.

6159. J. Hardman and J. Peake. Improvements in retort-charging devices. April 10.

6374. J. Guenet. Ozonising apparatus. Complete Specification. April 14.

6387. W. Heyes. Improvements in apparatus for concentrating acids and other liquids. April 14.

6405. J. R. Whiting and W. A. Lawrence. Improvements in methods for the recovery and utilisation of certain vaporised solvents. Complete Specification. April 14.

6488. P. M. Pinal, V. Letiauplier, and C. L. Pinal. Improvements in liquid gauges. Complete Specification. April 15.

6587. H. Hencke. Improvements in the method of and in apparatus for drying and evaporating. April 16.

COMPLETE SPECIFICATIONS ACCEPTED.*

1890.

6433. G. E. Davis and A. R. Davis. Furnace or heating chamber for conducting chemical operations. April 22.

8167. G. Moffat and S. Stuttaford. Apparatus for consuming smoke and saving fuel. April 1.

8168. G. Moffat and S. Stuttaford. Apparatus for delivering air into furnaces. April 1.

8523. E. F. Paddon. Furnaces. April 15.

8707. J. von Langer and L. Cooper. Gas furnaces for metallurgical and other purposes. April 22.

8790. W. R. Watson and R. A. Robertson. Apparatus for evaporating, concentrating, and distilling liquids. April 15.

9181. The Lucigen Light Co., Lim., and T. M. Jarmain. An oil flame furnace. April 22.

9685. G. Cox. Metal drums for carrying oil and other liquids. April 15.

10,116. F. R. Pemberton. Composition for preventing the passage of heat through bodies, deadening of sounds; and method of applying same. April 15.

14,370. A. Dannenberg. See Class II.

1891.

4292. The Brins Oxygen Co., Lim., and K. T. Murray. Apparatus for automatically changing the flow of fluids through pipes or passages. April 22.

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

4761. W. Bagley and J. W. Bagley. Improvements in and connected with the manufacture of gas for heating purposes. March 17.

4834. A. Lutschmannig. An improved manufacture of fire-lighter or fire-lighting material. Complete Specification. March 18.

5022. J. Moeller. An improvement in incandescent illumination, and apparatus for that purpose. March 20.

5036. W. P. Thompson.—From J. M. A. Gerard, France. Improvements in the treatment and desiccation of peat. March 20.

5037. R. C. W. Malthby. An improved artificial fuel. March 20.

5038. R. C. W. Malthby. An improved coke oven. March 20.

5187. F. Tschöfen. Improvements in the manufacture of candles. March 23.

5207. T. Thorp and T. G. Marsh. Improvements in the purification of gas. March 24.

5212. W. H. Munns.—From E. de Beauharnais, United States. Improvements in the art of manufacturing illuminating gas. March 24.

5217. J. T. Key. Improvements in the manufacture of gas for illuminating and other purposes, and apparatus therefor. March 24.

5299. B. H. Thwaite. Improvements in the production of combustible gases, and in apparatus therefor. March 25.

5468. J. Russell and J. C. W. Stanley. Improved manufacture of artificial fuel. March 26.

5468. W. H. Wilson. Improvements in or connected with the manufacture of illuminating gas. March 28.

5489. M. Mackay. Improvements in purifying gas and in apparatus therefor. March 28.

5701. O. W. Ketchum. Improvements in gas generating furnaces or gas producers. April 2.

5960. B. J. B. Mills.—From E. L. Clarke, Canada. Improvements in machinery for the manufacture of peat fuel. April 7.

6134. J. Laing. Improvements in the distillation of mineral oils and like bodies, and in apparatus therefor. April 10.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

5239. J. Blum. Instantaneous production of water gas. April 8.

7744. C. B. Newton. Apparatus for automatically delivering any proportionate quantity of oxygen, air, or other gaseous bodies into gas purifiers or other vessels, pipes, or conduits, irrespective of any pressure in such gas purifiers, &c. April 15.

8274. P. Shuttleworth. Manufacture of fire kindlers. April 15.

8535. S. Pitt.—From E. J. Jerzmanowski. Process and apparatus for the manufacture of illuminating gas. April 22.

9199. J. Bowing. Manufacture of fuel from coal-slack and similar substances, and obtaining tar products. March 25.

9320. T. Travers. Gas burners and apparatus for naphthalising gas. April 22.

12,639. R. Schimper. Manufacture of artificial fuel. March 25.

11,370. A. Dannenberg. Method of firing periodically and continuously worked chamber and annular furnaces. March 25.

11,832. J. H. W. Stringfellow. Treatment of liquid hydrocarbons. March 25.

17,159. T. G. Springer. Manufacture of gas. April 8.

1891.

974. B. H. Thwaite. Generating, heating, and lighting gases from liquids and solid hydrocarbons, and apparatus therefor. April 22.

1682. J. Bowing. Coking processes. April 8.

2021. P. F. Macallum.—From J. C. Reissig and J. Landin. Separating carbonic acid from other gases, especially in the production of lighting and heating gases free from carbonic oxide. March 25.

2452. L. André. Hydraulic mains for gas-making apparatus. April 22.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, &c.

APPLICATION.

6134. J. Laing. See Class II.

IV.—COLOURING MATTERS AND DYES.

APPLICATIONS.

4688. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik, Germany. The manufacture and production of new mordant-dyeing colouring matters related to the rosaniline series. March 16.

1871. B. Willeox.—From The Farbenfabriken vormals F. Bayer and Co., Germany. Improvements in the manufacture of colouring matters derived from anthraquinone. March 18.

5403. R. Holliday and Sons, Limited, T. Holliday, and P. R. E. Seidler. Improvements in the manufacture of a sulpho acid of alpha naphthol and of colouring matters therefrom. March 21.

5404. R. Holliday and Sons, Limited, T. Holliday, and P. R. E. Seidler. Improvements in the manufacture of azo-colouring matters. March 21.

5422. B. Willeox.—From F. von Heyden, Nachfolger, Germany. Improvements in the manufacture or production of ortho-oxy-diphenylcarbon acid. March 21.

5184. J. Y. Johnson.—From F. von Heyden, Nachfolger, Germany. Process for the production of mono-bromo and di-bromo-para-oxy-benzoic acid, suitable for conversion into proto-catechuic acid, pyro-catechin, and the like. March 23.

5269. W. Majert. Improvements in the manufacture of aromatic glyceoll derivatives. March 24.

5437. W. Sherwood. A new or improved composition of ink for reproduction of copies by the manifold process and the like. March 26.

5904. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brünig, Germany. Improvements in the production of black colouring matters. April 6.

5984. B. Willeox.—From The Farbenfabriken vormals F. Bayer and Co., Germany. Improvements in the manufacture or production of azo-colouring matters. April 7.

6268. J. Dawson and R. Hirsch. The manufacture of new raw materials for the production of colouring matters. April 13.

6376. Brooke, Simpson, and Spiller, Lim., and A. G. Green. The production of new bases and of azo-colouring matters therefrom. April 14.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

6875. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik. Manufacture of sulpho acids of a red basic naphthalene colouring matter. April 8.

8506. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brünig. Production of a yellow colouring matter. April 8.

8530. B. Willeox.—From The Farbenfabriken vormals F. Bayer and Co. Production of azo colours upon fibres. April 8.

8725. B. Willeox.—From The Farbenfabriken vormals F. Bayer and Co. Manufacture of new derivatives of alizarin and its analogues. April 15.

9080. J. Dawson and R. Hirsch. Manufacture of phenol ether and oxydiphenyl, their homologues, and analogues. April 22.

9258. O. Imray.—From H. K. Marlburg. Production of colouring matters. April 22.

9530. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brünig. Production of blue-green colouring matters. April 22.

9537. J. Y. Johnson.—From The Badische Anilin und Soda Fabrik. Manufacture of substantive dyestuffs, and new materials therefor. April 22.

10,047. O. Imray.—From the Society of Chemical Industry, Switzerland. Production of colouring matters. April 1.

1891.

3263. J. C. L. Durand, D. E. Hueguenin, and A. J. J. d'Andiran-Koechlin. Manufacture of colouring matters derived from pyrogallie acid, and their application to dyeing and printing. April 22.

V.—TEXTILES, COTTON, WOOL, SILK, &c.

APPLICATION.

5460. S. Stern. An improved composition, applicable to wool, shoddy, or mixed with cotton and other suitable material for spinning. March 23.

6294. J. Dawson. An improvement in dyeing mats, carpets or other fabrics of fibre, wool, yarn, silk, or any other material. April 13.

6663. A. George. Improvements in cleansing wool and similar materials. Complete Specification. Filed April 17. Date applied for October 31, 1890, being date of application in France.

6698. J. G. Smith.—From F. Döller, Germany. Improvements in the process of water-proofing textile materials. April 18.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

8520. P. A. Favier. Machines for decorticating ramie and other textile plants. April 8.

17,342. B. Tettweiler. Fabrics composed mainly of fibrous material. March 25.

1891.

2348. J. B. Barton. Process for the manufacture of granite linoleum. March 25.

2808. W. Barton. Utilising leather waste, and preparing therewith a material for covering floors, roofs, &c. March 25.

3447. T. Mitchell. Manufacture of linoleum and like floorcloths. April 1.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

4754. E. Bentz. A new or improved method of fixation of the chrome mordant employed in dyeing and calico printing. March 17.

4928. G. Young and W. Crippin. Improvements in arrangements and mechanism or apparatus for dyeing and bleaching and otherwise treating cotton, wool, silk, and other fibrous materials in the raw and manufactured or partly manufactured state. March 19.

5515. C. F. S. Rothwell. Improvements in the method of and apparatus for applying the liquor used for fixing basic aniline dyes, and other dyes fixed in a similar manner, on cotton piece goods and the like. March 31.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

7202. P. Cavaillès. Process and apparatus for dyeing wool. April 1.

8183. J. M. Campbell. Process and apparatus for colouring, sizing, and otherwise treating paper, applicable for filling and treating woven fabrics. April 1.

8270. E. Sutcliffe and G. E. Sutcliffe. Apparatus for washing, dyeing, and treating textile materials. April 1.

8530. B. Willecox.—From The Farbenfabriken vormals F. Bayer and Co. See Class IV.

8799. A. North. Black piece dyeing for improving the colour of warp or weft in mixed fabrics of wool and cotton. April 15.

8809. W. L. Wise.—From Favre and Braun. Treatment of fabrics printed or dyed with several colours. March 25.

1891.

2533. H. Thies and F. Cleff. Dyeing or printing in aniline black or analogous colours. March 25.

2993. J. Leitz and W. Weise. Printing and shaping textile materials. April 15.

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

4661. W. Mills. Improvements in the manufacture of alkali, and apparatus therefor. March 16.

4712. J. Pedder. Using a combination of sulphuric acid and hydrochloric acid for the decomposition of chlorides, sulphides, sulphates, and of sulphuretted hydrogen. March 17.

4730. C. Marriott. Improvements in apparatus used in the manufacture of sulphate of ammonia. March 17.

4820. G. T. Beilby. Process and apparatus for the manufacture of cyanides. March 18.

4878. J. M. Macdonald. A new and improved method of liquefying carbonic acid gas and storing the same in apparatus therefor. March 18.

5352. F. M. Lyte. Improvements in the production of alkaline carbonates, and chlorine and their derivatives. March 25.

5354. J. J. Hood and A. G. Salamon. Improvements in the manufacture of cyanogen compounds, and the treatment of substances used therein. March 25.

5519. M. W. Beylikgy, C. J. Everett, and C. A. Collins. Alkalino-magnesian silicate compound. Complete Specification. March 31.

5547. C. Kellner. Improvements in apparatus for electrolytic decomposition. Complete Specification. March 31.

5748. A. Moss and E. Newton. Economical production of carbonic acid gas. April 3.

5777. W. T. Bruce. Improvements in the manufacture of sulphuric acid and apparatus therefor. April 3.

5788. W. Feld. Improvements in the manufacture of sodium and potassium carbonates, sulphur, and sulphuric acid, and in apparatus therefor, applicable also to other purposes. April 3.

5801. M. Royon. An apparatus to produce sulphuretted hydrogen. April 4.

5819. D. Rowat and J. Fullerton. Improvements in and relating to the treatment of pickles, and apparatus therefor. April 4.

5844. A. G. Haddock and J. Leith. Improvements in or appertaining to the manufacture of alkali. April 4.

6388. P. J. B. Vincent. Improvements in the manufacture of salt in blocks or cakes. April 14.

6415. M. N. d'Andria. Improvements in utilising waste acid residues from the "pickling" of iron, and obtaining useful products therefrom, the said improvements being also applicable to the treatment of sulphate of iron and of chloride of iron. April 15.

6500. J. Kolb. Improvements in the production of chlorine. April 15.

6509. J. W. Wilson and C. H. G. Harvey. The manufacture of ferric chloride from waste pickle from galvanising works. April 16.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

6333. F. M. Lyte. Production of magnesian oxychloride. March 25.

7058. J. Y. Johnson.—From J. Marx and Dr. Weller. Process and apparatus for liquefying and storing chlorine. April 22.

7764. D. J. Playfair. Obtainment of cyanides and ferrocyanides. March 25.

1891.

2224. H. H. Lake.—From J. Massignon and E. Watch. Manufacture of chromates, bichromates, and other chromium compounds. April 8.

2812. J. N. Zeitler. Converting carbonate of lead, obtained by decomposition of sulphate of lead or other compound of lead, with carbonate of sodium into basic salt. April 15.

VIII.—GLASS, POTTERY, AND EARTHENWARE.

APPLICATIONS.

1657. L. Forester and H. J. Gneathatch. A composition for economy in placing glazed tiles or plaques, &c., majolica, and earthenware in kilns or ovens; also washing kilns. March 16.

5063. F. Quéry. Improvements in kilns for use in the manufacture of pottery, porcelain, and earthenware, and other similar goods. March 21.

5324. W. Walker. Improvements in the production of glass-making materials. March 25.

5566. R. Lindsay. See Class X.

5782. A. J. Boulton. From L. T. Karras and G. Hoffmann, Germany. Improvements in the manufacture of glass letters and the like. Complete Specification. April 3.

5787. C. H. Edwards. Improvements in the manufacture of gas retorts, drain pipes, and other like earthenware or clayware. April 3.

5897. J. Lauder and W. Thomson. Improvements in bath walling and flooring tiles. April 4.

6118. H. Warrington. Improvements in kilns or ovens for bricks, earthenware, porcelain, and similar material. Complete Specification. April 9.

6265. The Company Glasstechnisches Laboratorium Schott and Genossen and Otto Schott. New method of manufacturing toughened glass wares (composite glass). April 11.

6257. W. C. Gibson. Improvements in kilns for bisuiting and burning glazed and enamelled clay goods. April 13.

6524. W. W. Pilkington. Improvements in kilns for annealing plate glass. April 16.

6525. W. W. Pilkington. Improvements in apparatus for rolling glass. April 16.

6691. W. W. Pilkington. Improvements in kilns for annealing plate glass. April 18.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

1356. A. J. Wilkinson. Ovens for firing pottery. March 25.

5979. H. M. Ashley. Manufacture of ceramic ware, and apparatus therefor. March 25.

7115. D. Rylands. Machinery for manufacture of bottles and other glass ware, and method of working same. April 15.

7822. D. Y. Cliff. Means for effecting correct designs in decorative tiles. March 25.

1891.

1704. H. Warrington. Ovens or kilns for burning bricks, tiles, or the like. March 25.

3365. H. B. Lake. From E. Sochaczewski. Production of a plastic moulding material, and articles therefrom. April 1.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

1672. E. Olson. Improvements in stucco for plastering. Complete Specification. March 16.

4738. W. Thompson. Improvements in calcining limestone. March 17.

4750. The Société Anonyme des Ardoisiers de Deville and V. van der Heyden. A new manufacture of material suitable for building, paving, and other purposes from waste pieces or débris of slate. March 17.

4990. J. V. Boyd-Wilson. Improved compositions for use in building constructions, fire-resisting constructions, and the like. March 20.

5599. J. C. Bloomfield. A new or improved material, applicable for ceilings, wall linings, cement slabs, and for other purposes. April 1.

5709. O. Clausen. Improvements in the manufacture of fireclay and magnesian bricks, and in kilns for firing same. April 2.

5719. A. J. Boulton. From L. Grote, Germany. Improved manufacture of artificial stone. Complete Specification. April 2.

5810. T. Hydes. Improvements in the manufacture of hydraulic cement, concrete, dry mortar, bricks, tiles, pipes, and the like. April 4.

6011. J. Craven. Improvements in or connected with kilns for drying and burning bricks or other articles or materials. April 8.

6118. H. Warrington. See Class VIII.

6227. T. Potter. Improvements in fire-resisting floors. April 11.

6244. R. H. Hepburn. Improvements in roofs, walls, and other parts of buildings, and in slabs, sheets, or tiles for the same. April 11.

6389. R. A. Cheesbrough. Improvements in the preservation of wood and iron imbedded or buried in the earth. Complete Specification. April 14.

6532. J. Jackson. Improved manufacture or production of decorative material, more especially intended for application to walls, ceilings, or like surfaces. April 16.

6630. J. Griffiths. Improvements in street and other pavements. April 17.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

6952. C. Kellner. Coating iron, steel, or other metals with Portland or other cement. March 25.

8113. J. Hartnell. Manufacture of artificial stone. April 1.

8519. O. Prinz. Manufacture and treatment of cement. April 15.

8919. D. Wilson. Manufacture of cement, and apparatus therefor. April 15.

1891.

2865. H. F. Williams. Composition for paving, roofing, and building purposes. March 25.

2894. O. Clausen. New or improved paving. April 8.

3551. R. R. Courten. Plaster slabs. April 8.

4672. E. Olson. Stucco for plastering. April 22.

X.—METALLURGY, MINING, Etc.

APPLICATIONS.

4644. J. O. Arnold. Improvements in the processes of manufacture of steel ingots, steel castings, and ingot iron, and in apparatus and appliances employed therein. March 16.

4695. W. A. Baldwin. Improved process and apparatus for alloying metals. Complete Specification. March 16.

4696. J. C. Butterfield. Improvements in the treatment of tinned iron for the recovery of the tin and other products. March 16.

4713. H. Reusch and B. Preen. Improvements in or relating to the manufacture or casting of hard metal or chilled rolls. March 17.

4793. W. B. Middleton. Improvements in the treatment of steel. Complete Specification. March 17.

4955. I. A. F. Bang and M. C. A. Rudlin. Process for separating the tin from tin-plate waste, used preserve tins, and the like. March 19.

4972. J. A. Fletcher, S. Fletcher, and J. Fletcher. See Class I.

5107. H. Warrington. Improvements in fire grates for puddling, heating, and similar purposes. Complete Specification. March 21.

5128. A. Gutensohn. Improvements in the dry metallurgical treatment of sulphide ores such as galena. March 21.

5169. J. F. Duke, A. S. Bishop, and I. Symons. Improvements in the production of aluminium. March 23.

5170. J. F. Duke, A. S. Bishop, and I. Symons. Improvements in the production of aluminium bronze. March 23.

5171. J. F. Duke, A. S. Bishop, and I. Symons. An improved metallic alloy. March 23.

5242. W. R. Hinsdale. Process of casting ingots. Complete Specification. March 24.

5527. T. H. Mallaband. Improvements in melting furnaces. March 31.

5566. R. Lindsay. An improved furnace for heating branding irons and annealing metals and glass. March 31.

5642. W. Sowerby and E. Casper. Improvements in casting metals. April 1.

5822. G. A. Herdman. Improvements in treating waste products resulting from the smelting of ores and in producing a valuable product therefrom, or from analogous compounds, and improved apparatus in connexion therewith. April 4.

5851. W. Sowerby and E. Casper. Improvements in casting metals. April 6.

6013. R. Crosthwaite and J. B. Spence. Improvements in the manufacture of iron amalgams. April 8.

6080. J. D. Wilson. Improvements in cupolas. April 9.

6152. G. Jones. A new or improved fettling for puddling furnaces and steel-making furnaces. April 10.

6233. J. Lang and F. H. Wigham. A process for protecting iron and steel wire against corrosion. April 11.

6235. J. Lang and F. H. Wigham. A process for protecting iron and steel wire against corrosion. April 11.

6246. W. S. Lockhart and E. W. Streeter. An improved process and apparatus used therein for the separation of metals, precious stones, or other minerals from gangue or other matter mixed therewith. April 11.

6303. J. H. Darby. Improvements in the manufacture of steel. April 13.

6323. E. Taussig. Improvements in apparatus for smelting and casting. Complete Specification. April 13.

6479. W. T. Rickard. Improvements in the mechanical and chemico-metallurgical treatment of copper, the precious, and other metallic ores. April 15.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

2901. F. J. Jones. Making tubes, cylinders, and other hollow ware of copper, alloys, and aluminium. April 22.

6645. J. H. Lancaster and M. R. Couley. Manufacture of iron or steel. April 1.

7070. J. Heston and G. H. Holden. Manufacture of steel and iron, and apparatus therefor. March 25.

7253. W. Hodge. Converting iron into steel, or steelifying wrought-iron objects. April 8.

8352. W. McDermott. Apparatus for concentrating and separating ores, &c. April 1.

8707. J. von Langer and L. Cooper. See Class I.

8884. J. W. MacFarlane. Extracting gold from auriferous ores by an improved method of amalgamation. April 15.

8922. T. Peters. Application of the iron residues which result from the reduction of organic nitro-compounds. April 15.

9182. C. R. Weston. Means and apparatus for extracting gold and other precious metals from their ores. April 22.

13,486. A. Schneller and A. Astfalie. Production of pure aluminium. April 1.

17,186. S. B. Evans. A gas ingot-heating furnace. April 8.

17,663. E. P. Martin and E. James. Method and means for preparing moulds for casting pig iron, and for breaking the pigs and separating them from the "sow." April 8.

18,066. Davies Bros. and Co., Lim., and M. Bayliss. Galvanising sheet metal. April 15.

19,180. J. C. Bayles. Method and apparatus for welding iron or steel sheets or plates. March 25.

1891.

251. W. R. Hinsdale. Process for forming ingots. April 22.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY

APPLICATIONS.

4757. T. L. Wilson. Improvements in the electric reduction of aluminium and other metals, and in the production of alloys thereof. March 17.

4781. W. J. Engledue. A new or improved solution or electrolytic fluid for galvanic batteries. March 17.

4860. H. Howard. Improvements in apparatus for heating and welding by the electric arc. March 18.

4869. H. H. Lake.—From L. A. W. Desruelles, France. Improvements relating to primary and secondary electric batteries, and to the manufacture of plates or electrodes for use therein. March 18.

4877. H. H. Lake.—From E. A. G. Street and L. A. W. Desruelles, France. Improvements relating to plates or electrodes for primary and secondary batteries, and to the production of compounds or agglomerates for the manufacture of such plates or electrodes. March 18.

4949. J. Y. Johnson.—From A. Tardy, France. Improvements in galvanic batteries. March 19.

5167. F. E. Elmore and A. S. Elmore. An improvement in the manufacture of tubes by electrolysis. March 23.

5637. R. W. Barker.—From M. G. Farmer, United States. Improvements in electric converters. April 1.

5638. W. A. Crowder. Improvements in electric batteries. Complete Specification. Filed April 1. Date applied for October 7th, 1890, being date of application in United States.

5690. H. C. Bull. Improvements in and connected with electric batteries. April 2.

5918. H. I. Harris and W. H. Power. Improvements in electric batteries. April 6.

5953. W. A. Byron and E. George. Improvements in and relating to voltaic batteries. April 7.

5972. W. Sillery. Improvements in electric storage batteries. April 7.

5995. F. E. S. D'Odiardi. Improvements in liquid electrodes. April 7.

5996. F. E. S. D'Odiardi.—Improvements in magneto-voltaic and static electrodes. April 7.

5999. J. Greenwood. Improvements in and relating to the manufacture or production of chlorine and sodium amalgam. April 7.

6029. W. H. Walenn and I. A. Timmis. Improvements in electro depositing copper, brass, and bronze, parts of which improvements are also applicable to other purposes. April 8.

6030. W. H. Walenn and I. A. Timmis. Improvements to electro depositing copper, brass, or bronze. April 8.

6243. S. M. L. Patz and R. Grebner. Improvements in galvanic batteries. April 11.

6247. J. Y. Johnson.—From F. Gendron, France. Improvements in automatic regulating apparatus employed in connexion with galvanic batteries. April 11.

6502. J. von der Poppenberg. Improvements in galvanic batteries. April 15.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

6266. J. Marx. Means for use in electrolysis. April 1.

7513. W. L. Wise.—From P. Schoon. Manufacture of electrodes for secondary batteries. April 1.

8534. N. De Benardos and Lloyd. Secondary batteries. April 8.

9361. T. L. Willson. Electric reduction of metals, and apparatus therefor. April 22.

13,463. J. Mosely. Zincs for galvanic batteries. March 25.

18,180. Sir C. S. Forbes, Bart. Primary batteries, and apparatus connected therewith. April 22.

19,942. W. P. Thompson.—From F. Marx. Galvanic batteries. March 25.

20,986. H. H. Lake.—From H. Lemp. Apparatus for electrically welding and otherwise working metals. March 25.

1891.

1007. E. Ferraris. Apparatus for separating ores and metals by the aid of electricity. April 1.

1425. A. J. Boulton.—From W. Roberts. Storage batteries. April 1.

3336. H. H. Lake.—From H. Lemp and L. M. Schmidt. Process and apparatus for welding metals by electricity. April 1.

3349. M. W. Dewey. Electric welding apparatus. April 22.

3589. H. H. Lake.—From W. R. H. Dowse. Electric batteries. April 15.

XII.—FATS, OILS, AND SOAP MANUFACTURE.

APPLICATIONS.

5405. E. Azémar. An improved compound to be used for removing grease of all kinds from wool and woollen cloth, washing all kinds of cloth, and cleaning household utensils and woodwork. March 26.

5870. J. E. A. Bokeland. Improved preparation for use as a substitute for linseed oil in the mixing of pigments. Complete Specification. April 6.

5951. R. F. Hallock. A new or improved washing preparation. April 7.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

7142. H. Stern. Decolourising mineral, animal, and vegetable oils, fats, and the like by means of silicic acid. March 25.

7696. F. N. Mackay. Appliances for cooling oil and like liquids. April 22.

XIII.—PAINTS, PIGMENTS, VARNISHES, AND RESINS.

APPLICATIONS.

5396. R. J. Friswell. Improvements in the manufacture of lamp black and similar substances. March 26.

5501. W. Smith and W. Elmore. Improvements in the production of white lead or basic carbonate of lead from galena or sulphide of lead ore, or from suitable residual products or substances containing sulphide of lead. March 28.

5624. W. P. Thompson.—From A. Flugge. Improvements in and relating to the production of a solution of myrrhic resin. April 1.

5681. C. A. Burghardt. Improvements in pigments having a lead basis. April 2.

5977. J. Robson. Improvements in or appertaining to preservative coatings for iron or other structures. April 7.

6063. W. Jones. Improvements in the manufacture of blue for laundries, distempering, and other purposes. April 8.

6306. W. P. Thompson.—From A. Flugge, Germany. Improvements in and relating to the production of a solution of myrrhic resin. April 13.

6366. S. Springer. A protective compound. April 14.

6548. R. Wilson. Blues and greens,—colour pigments. April 15.

6683. R. J. White. Improvements in the manufacture of white lead. April 18.

COMPLETE SPECIFICATION ACCEPTED.

1890.

6805. W. P. Thompson.—From A. F. von Pereira. Improvements in paints, colours, varnishes, and distempers, and method of applying them. April 1.

XIV.—TANNING, LEATHER, GLUE, AND SIZE.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

19,216. C. L. Lawrence. Making leather boards, soles, &c. waterproof. April 8.

1891.

2808. W. Barton. See Class V.

XV.—AGRICULTURE AND MANURES.

APPLICATIONS.

5111. O. Jachne. Improvements in process for making superphosphatic manure. Complete Specification. March 21.

5357. H. H. Lake.—From A. Briart and P. Jacquemin, Belgium. An improved method for enriching calcareous phosphates, and for manufacturing superphosphates and various by-products. March 25.

XVI.—SUGARS, STARCHES, GUMS, Etc.

APPLICATIONS.

5191. A. Wohl and A. Kolrepp. Improvements in the production of invert sugar. March 24.

5236. A. Schneller and W. J. Wisse. Improvements in the refining or extraction of sugar from raw sugar solution, juice or molasses. March 24.

5683. R. Warwick. An improved prepared laundry starch, white and in various tints of colour, and for rendering textile fabrics less inflammable. April 2.

COMPLETE SPECIFICATION ACCEPTED.

1890.

5282. G. F. Redfern.—From M. Wienrich. Manufacture of sugar. April 1.

XVII.—BREWING, WINES, SPIRITS, Etc.

APPLICATIONS.

4680. A. von Sigmond. A method of producing yeast and spirit from materials containing starch. March 16.

4744. E. H. Wagner. An improved temperance beverage or beer. March 17.

5004. J. Mitchell. Improvements in machinery or apparatus for drying distillers' or brewers' draff or dreg, but which is also applicable for drying other similar materials. Complete Specification. March 20.

5420. W. S. Squire. Obtaining lactic acid from distillers' spent wash. March 26.

5700. J. Takamine. Composition of matter for use as an artificial food and fertiliser of moyashi or ferment cells, and processes for producing Moyashi, Moto, Koji, and fermented alcoholic liquors. Complete Specification. April 2.

5853. W. Heasman. Improvements in or relating to means for the hot aëration of wort. April 6.

6317. M. Schwab. Improved method of and apparatus for regulating the egress of spent liquor from distillatory apparatus. Complete Specification. April 13.

6354. A. H. Allen and W. Chattaway. An improved method of maturing spirits. April 14.

6401. J. P. Cavallier. An improved method of ageing alcoholic liquors. April 14.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

6075. F. M. Maynard. The aëration of yeast for exciting alcoholic fermentations. March 25.

7098. A. J. Boulton.—From La Société Générale de Maltose. Manufacture of maltose, or the fermentation of amylaceous matter. April 1.

7880. H. T. Brown, G. H. Morris, and E. R. Moritz. Preparing raw grain or other amylaceous substances for mashing. April 1.

1891.

2936. H. J. Haddan.—From J. Batalle. Improving wine and other alcoholic liquors. April 1.

XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, AND DISINFECTANTS.

APPLICATIONS.

A.—Chemistry of Foods.

4706. H. Gardner.—From E. Serrant, France. Improved method of preparing bread biscuits specially adapted for preservation, to be called "Biseroute" or condensed bread, and in moulds therefor. March 16.

4837. D. Tallerman. Improvements for the slaughter of animals and the preservation of perishable foods. March 18.

4967. C. G. Campbell. Destroying animal life in cheese, and preventing its recurrence. March 20.

5196. C. B. Lesser. Improved method of or process for the preparation of condensed milk. Complete Specification. March 24.

5380. J. B. Marshall. Improved means of preserving eggs. March 26.

6255. J. Dunn and W. Duon. Improvements in the manufacture of cattle food. April 13.

6417. A. J. Boulton. From J. J. Sheppard, France. Improvements in the treatment of cereals for food and other purposes, and in apparatus therefor. April 15.

B.—Sanitary Chemistry.

5330. E. E. Scruby. Improved process for purifying sewage effluents and other impure liquids, and apparatus therefor. March 25.

5358. S. Delepine and A. F. B. Gomess. A new method of and apparatus for the removal of smoke from chimneys for the purpose of preventing contamination of the air by the products of combustion, or of removing these products after they have become mixed with the air, so as to prevent the production of so-called yellow and black fogs; part of which apparatus is also applicable for collecting the carbon from gas and other lights. March 25.

5908. E. E. Dulier. A method of destroying smoke, and apparatus for that purpose. April 6.

6031. P. H. Williams. Improvements in method and means of and apparatus for deodorising or purifying and utilising sewage. April 8.

C.—Disinfectants.

4772. E. Serrant. A new compound for general healing and for disinfecting purposes, to be known as "Service acid." March 17.

5263. J. Y. Johnson.—From F. von Heyden, Germany. Improvements in the production of salicylic acid derivatives containing chlorine and sulphur. March 24.

COMPLETE SPECIFICATIONS ACCEPTED.

A.—Chemistry of Foods.

1890.

6102. W. S. Simpson. Means and appliances for preserving flesh food. April 1.

B.—Sanitary Chemistry.

1890.

6660. M. M. Brophy. Furnaces for destroying organic substances. March 25.

XIX.—PAPER, PASTEBOARD, Etc.

APPLICATIONS.

5240. J. Valetou. New or improved anti-nicotine cigarette paper. March 24.

5310. R. Aitken. Improvements in the treatment of paper or other substances for fixing or protecting water-colour drawings or printings or the like thereon, and also for rendering paper or other substances impervious to water. March 25.

6423. W. Andrew. Improvements in boilers or digesters used in the manufacture of paper pulp. April 15.

6589. C. Lenz. Improved manufacture of paper and cardboard. April 16.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

6644. J. Johnston and G. Johnston. Treatment of paper-making fibre materials. April 22.

1891.

2349. J. C. Joel and E. Ryan. Purifying wood pulp, and apparatus therefor. April 1.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

APPLICATIONS.

5222. A. Schneller and W. J. Wisse. Improvements in the formation of ozone in presence of air or oxygen, and apparatus therefor. March 24.

5425. A. M. Clark.—From The Verien für Chemische Industrie, through their agents, Wirth and Co., Germany. An improved method for the production of acetic anhydride and other anhydrides of the fatty acid series. March 26.

5981. J. Le Roy Webber. Improved manufacture of pepsine. Complete Specification. April 7.

6234. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Bünning, Germany. Production of basic gallate of bismuth. April 11.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

8454. T. H. Williams and W. H. Simons. Production and application of a solution of calcium phosphate in carbonic acid water for use in pharmacy. April 22.

15,687. F. Valentiner. Manufacture of artificial musk. April 8.

1891.

115. G. Link and R. Avenarius. Manufacture of artificial perfumes. April 1.

XXI.—PHOTOGRAPHIC PROCESSES AND MATERIALS.

APPLICATIONS.

5298. T. D. Ashplant. Application of talc or mica as a substitute for glass, celluloid, paper films, and other things now in use for photographic purposes, dry plates, transparencies, and lantern slides. March 25.

5833. J. Y. Johnson.—From P. Mercier, France. Improvements in the manufacture or production of sensitive paper for photographic purposes. April 4.

6472. G. T. Teasdale-Buckell. Improvements in the production by the aid of photography of surfaces for printing in colours, and in the means and apparatus employed therein. April 10.

6340. G. T. Teasdale-Buckell. Improvements in the production, by the aid of photography, of surfaces for use in printing in colours, and in means or apparatus employed therein. April 14.

6331. G. T. Teasdale-Buckell. Improvements in the production, by the aid of photography, of surfaces for use in printing in colours, and in means employed therein. April 14.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

5742. E. Fairweather. Developing photographic plates or other substances carrying a sensitive film. April 1.

7453. A. G. Green, C. F. Cross, and E. J. Bevan. Process for photographing by means of organic compounds. April 15.

9538. W. Rebikow. Manufacture of emulsions and other materials sensitive to light. April 15.

XXII.—EXPLOSIVES, MATCHES, ETC.

APPLICATIONS.

4797. H. Maxim. Improvements relating to the manufacture of nitro-substitution compounds of cellulose, and to apparatus therefor. March 17.

5010. H. Maxim. Improvements relating to the manufacture of nitro-substitution compounds of cellulose, and to apparatus therefor. March 20.

5027. E. von Brauk. New or improved explosive compositions. March 20.

5657. H. Maxim. Improvements relating to the restoration or strengthening and utilisation of the weakened or spent acids from the manufacture of pyroxyline or gun-cotton and nitroglycerin, and to apparatus therefor. April 1.

5824. C. H. Curtis and G. G. André. Improvements in explosives. April 4.

5843. A. Moselek and A. Brunner. An improved smokeless blasting compound. Complete Specification. April 4.

6128. J. Y. Johnson.—From The Dynamite Actiengesellschaft Nobel, Austria. Improvements in the manufacture or production of gunpowder or like explosives. April 9.

6129. J. Y. Johnson.—From The Dynamite Actiengesellschaft Nobel, Austria. Improvements in the manufacture or production of gunpowder or like explosives. April 9.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

5376. H. de Chardonnet. Processes and apparatus for the nitration and denitration of cellulose, and for regaining the acids employed. April 8.

6614. W. Hurst. Manufacture of wax matches, vestas, and tapers. April 1.

8811. H. Kolf. Manufacture of gunpowder. April 15.

OF THE

Society of Chemical Industry:

A MONTHLY RECORD

FOR ALL INTERESTED IN CHEMICAL MANUFACTURES.

No. 5.—VOL. X.]

MAY 30, 1891.

[Non-Members 30/- per annum; Members 21/- per Set of extra or back numbers; Single Copies (Members only) 2/6.]

The Society of Chemical Industry.

Past Presidents:

Sir H. E. Roscoe, M.P., LL.D., V.P.R.S.	1881—1882.
Sir Frederick Abel, C.B., D.C.L., F.R.S.	1882—1883.
Walter Weldon, F.R.S.	1883—1884.
W. H. Perkin, Ph.D., F.R.S.	1884—1885.
E. K. Muspratt	1885—1886.
David Howard	1886—1887.
Prof. James Dewar, F.R.S.	1887—1888.
Ludwig Mond	1888—1889.
Sir Lowthian Bell, Bart., F.R.S.	1889—1890.

COUNCIL FOR YEAR ENDING JULY, 1891.

President: E. Rider Cook,

Vice-Presidents:

Sir Lowthian Bell, Bart., F.R.S.	Ludwig Mond.
R. Forbes Carpenter.	Dr. Hugo Müller, F.R.S.
Prof. James Dewar, F.R.S.	B. E. R. Newlands.
James Duncan.	Dr. W. H. Perkin, F.R.S.
David Howard.	Dr. Edu. Schunck, F.R.S.
S. H. Johnson.	J. C. Stevenson, M.P.

Ordinary Members of Council:

A. H. Allen.	Prof. R. Meldola, F.R.S.
L. Archbutt.	E. K. Muspratt.
S. B. Boulton.	T. L. Patterson.
Jno. Brock.	Jno. Pattinson.
Jno. Calderwood.	Jno. Spiller.
H. Grimshaw.	T. W. Stuart.

With the Chairmen and Secretaries of Sections.

Honorary Treasurer:

E. Rider Cook, East London Soapworks, Bow, E.

Honorary Foreign Secretary:

Dr. F. Hurter.

General Secretary: Charles G. Cresswell.

Offices:

NOTICES.

In accordance with the provisions of Rule 18 of the Bye-laws, notice is hereby given that those Members of Council whose names are placed in italics in the annexed list will retire from their respective offices at the forthcoming Annual General Meeting.

Professor J. Emerson Reynolds, F.R.S., has been nominated to the office of President; and Mr. E. Rider Cook has been nominated Vice-President under Rule 11.

Dr. John Evans, F.R.S., Mr. A. Norman Tate, and Sir John Turney, have been nominated Vice-Presidents under Rule 8.

The Treasurer and Foreign Secretary have been nominated for re-election.

Members are hereby invited to nominate fit and proper persons to fill four vacancies among the Ordinary Members of Council under Rule 18. Special nomination forms for this purpose can be obtained from the General Secretary upon application.

Extract from Rule 18.—"No such nomination shall be valid unless it be signed by at least ten Members of the Society who are not in arrears with their subscriptions, nor unless it be received by the General Secretary, at the Society's Office, at least one month before the date of the commencement of the Annual General Meeting, to the election to take place at which it refers. Nor shall any such nomination be valid if the person nominated be ineligible for election under Rules 12 or 15. No member shall sign more than one nomination form."

ANNUAL GENERAL MEETING.

Notice is hereby given that the next Annual General Meeting will be held in Dublin on Wednesday, Thursday, and Friday, the 8th, 9th, and 10th of July next. Detailed arrangements and the programme of proceedings appear in this issue. Tickets of membership will be issued in time for the meeting, and will form, as heretofore, vouchers for visits to works and excursions.

Post Office Orders should be made payable at the General Post Office, London, to the Honorary Treasurer, E. Rider Cook, and should be forwarded to him at Bow, unless it be desired to notify a change of address.

Members who require extra sets or back numbers of the Journal are requested to make application to the General Secretary only, to whom also changes of address should be communicated.

Authors of communications read before the Society, or any of its Local Sections, are requested to take notice that under Rule 41 of the bye-laws, the Society has the right of priority of publication for three months of all such papers. Infringement of this bye-law renders papers liable to be rejected by the Publication Committee, or ordered to be abstracted for the Journal, in which case no reprints can be furnished to the author.

Notice is hereby given, for the information of members and advertisers, that the advertisement columns of this Journal have been contracted for by Messrs. EYRE and SPOTISWOODE, the Society's printers and publishers, to whom all communications respecting them should be addressed.

The Secretary is instructed to negotiate for the purchase of copies of the Society's Journal for January and May 1883, and January, February, and April 1886. Members possessing odd copies of these numbers are particularly requested to communicate at once, stating price required, with Mr. Cresswell. The stock of all other numbers is at present sufficient for the Council's requirements.

LIST OF MEMBERS ELECTED, 22nd MAY, 1891.

- Beck, H., 22, Bush Lane, London, E.C., chemical agent.
 Brown, Cesar R., Anglo-Continental Guano Works, Victoria Docks, E., foreman.
 Caldecott, Wm. A., Eureka City, Barberton, S.A.R., assayer.
 Cameron, Jas., c/o Nobel's Explosives Co., Lim., Polmont Station, N.B., chemist.
 Cook, Jas. Williams, 30, Bury Street, St. Mary Axe, E.C., dyer.
 Denison, Joseph R., 1, Park View Terrace, Manningham, Bradford, Yorks, analyst.
 Doran, Robt. E., 1, Goldsmith Terrace, Bray, co. Wicklow, analyst.
 Eager, Wm., Fermoy, co. Cork, Ireland, mineral water manufacturer.
 Hatschek, Moritz P., 18, Featherstone Buildings, Holborn, W.C., chemical engineer.
 Hirsch, Dr. Robt., 17, Zetland Street, Huddersfield, chemical works manager.
 Meldrum, Jas. Jones, Atlantic Works, City Road, Manchester, engineer.
 Osborne, Jas., c/o Rio Tinto Co., Lim., 30, St. Swithin's Lane, E.C., general technical manager.
 Watson, Harry F., Erie, Pa., U.S.A., chemical and paper manufacturer.
 Wollheim, Hugo, 21, Ridgway Place, Wimbledon, Surrey, research chemist.
 Woulton, Wm. Jos., Lake View, Bessbrook, co. Armagh, bleacher.

CHANGES OF ADDRESS.

Hon. Local Sec. and Treasurer:

T. W. B. Mumford, 1, Glendale Villas, Sylvan Road, Wanstead, E.

The names in italics are those of members of Committee who retire at the end of the current Session.

The following have been elected to fill the vacancies, and will take office in July next:—*Committee:* C. F. Cross, J. Heron, W. Kellner, G. N. Stoker, and F. Napier Sutton.

SESSION 1890—91.

June 1st:—

Dr. S. Rideal and Mr. W. E. Voule.—"Gum Arabic and its modern Substitutes."

Mr. J. W. Lawbourn.—"The Quantitative Analysis of Light and Colour, founded on the Tintometer Colour Scales."

Meeting held Monday, April 6th, 1891.

MR. THOS. TYRER IN THE CHAIR.

THE ANALYSIS OF ILLUMINATING GASES.

BY VIVIAN B. LEWES.

DURING the past year I had occasion to make many analyses of coal-gas and water-gas carburetted with the hydrocarbons obtained by cracking various grades of petroleum oil, and at the outset of the work found so many difficulties that I conceived my experiences and the conclusions I arrived at may prove of practical utility to others employed on work of similar character.

The beautiful methods devised and perfected by Bunsen are undoubtedly far too tedious to allow of their being used for practical purposes, whilst many of the newer processes and forms of apparatus which have been introduced in order to supply the needs of commercial analysis are so fraught with error that the results obtained are more likely to create confusion than to serve any useful end. Careful consideration of the forms of gas analysis apparatus in general use led me to the adoption of the form devised by Mr. J. E. Stead, which seems to me to combine ease of manipulation with reasonable accuracy in the results obtained, if only rational methods of procedure be observed in its use.

This form of apparatus is so well known amongst commercial analysts that a description of its form and the method of using it is unnecessary, the main principle being a combined eudiometer and measuring tube, in which mercury is employed as the "trapping fluid," the column of mercury being balanced by a second column, whilst the gas under analysis is passed into separate laboratory vessels in order to undergo absorption by the various liquids used, and is then passed back for measurement or for combustion by explosion into the eudiometer tube.

In the first analyses I made with this apparatus I was struck by the insufficiency of detail to be found in the various works on gas analysis, and also found that very wide discrepancies existed in the results obtained on making several analyses of the same gas, whilst other troubles, such as the almost impossibility of preventing traces of the absorbents coming in contact with the mercury used and

so rendering it impure, became a serious trouble in rapid working. Taking an ordinary illuminating gas or carburetted water-gas, the important constituents to be determined are hydrogen, hydrocarbons, carbon monoxide, carbon dioxide, nitrogen, and oxygen, whilst under certain conditions it is important to know the percentages of acetylene, sulphuretted hydrogen, and carbon disulphide present. The ordinary directions given in such standard works as the "Select Methods" are to first absorb sulphuretted hydrogen and carbon dioxide, then carbon monoxide, estimate ethylene by Nordhausen acid, and determine hydrogen, methane, and nitrogen by explosion, absorption, and difference. A far better process is given by Winkler in his "Handbook of Technical Gas Analysis,"† in which carbon dioxide is first determined by absorption with potassic hydrate, then the ethylene, propylene, butylene, &c. by bromine water, benzene by fuming nitric acid, oxygen by alkaline pyrogallate, carbon monoxide by cuprous chloride, and the hydrogen methane and nitrogen by explosion, absorption, and difference.

These two forms of analysis may be fairly taken as the types on which the analytical schemes given in all the text books are based, the chief variations being in introducing combustion of hydrogen by palladium asbestos or estimation of the residual gases after the absorptions, by explosion and calculation from contraction and carbon dioxide formed. None of these processes gave anything approaching concordant results in my experiments, and although with an ordinary coal-gas I was able to get two analyses of the same sample within a few per cent. of each other, carburetted water-gas gave such widely different results that it was evident that something was radically wrong. A consideration of the methods given above, and the results of the analyses soon showed that even with ordinary coal-gas the first method was absolutely useless, as the cuprous chloride used to absorb carbon monoxide was nearly as good an absorbent for unsaturated hydrocarbons and oxygen as the liquids usually employed for their determination, and that this was the case whether it be used in acid or ammoniacal solution; whilst a still more serious cause of error applies to all methods of analysis which I have seen suggested. All researches on the composition of coal-gas point to the presence of ethane, and probably of higher members of the marsh-gas series; whilst in carburetted gases they are undoubtedly present to a far greater extent.

Ethane, propane, and butane have all been shown to be present in small quantities; and as ethane gives double, propane, three times, and butane four times its own volume of carbon dioxide, it is evident that exploding with oxygen and taking the volume of carbon dioxide as representing marsh-gas, will undoubtedly give too high results with ordinary coal-gas, while with a carburetted gas it will render the whole analysis useless. Moreover, the free oxygen is next absorbed, and the remainder taken as nitrogen, whilst the hydrogen in the gas is determined by difference. The result is that the hydrogen is always far too low, not only because the volume of marsh-gas is too high, but because the residual nitrogen, having to bear the brunt of all the errors of analysis throughout some seven or eight absorptions, is also always too high. These palpable errors in the quantity of marsh-gas and hydrogen also render worthless the calculations of the carbon and hydrogen density of the gas, on which great stress has been laid, as showing the composition of the hydrocarbons present.

In order to eliminate as far as possible these serious sources of error, I made a series of experiments with a view of determining the best order in which to use the various absorptive liquids, and also to find how far an absorbent could be found for the ethane, propane, and butane.

Preliminary experiments showed that these latter were taken up by alcohol, olive oil, or paraffin, the alcohol having the disadvantage, however, of giving off vapours, which had to be carefully removed, whilst the olive oil,

from its greasiness, was inconvenient. Moreover, the paraffin, when properly prepared, is by far the best and quickest absorbent of the three, and has not these disadvantages.

In order to make the experiments as definite as possible solutions of known strength were employed, the following being found to be the most advantageous:—

Sodic hydrate.....	20 per cent. solution.
Alkaline pyrogallate..	10 grms. of pyrogallie acid in 150 cc. of 20 per cent. solution of sodic hydrate.
Bromine in potassic bromide.	Saturated solution of potassic bromide saturated with bromine and then diluted to twice its original volume.
Fuming nitric acid...	Sp. gr. 1.55.
Nordhausen sulphuric acid.	Containing as much SO ₃ as will dissolve in it at ordinary temperatures (15° C.).
Acid cuprous chloride.	Saturated solution.
Ammoniacal cuprous chloride.	The cuprous chloride precipitated by water from 200 cc. of the saturated acid solution is, after washing, dissolved in 150 cc. of water containing 10 grms. of ammoniac chloride and 50 cc. of 0.880 sp. gr. ammoniac hydrate.
Paraffin.....	A clear bright sample of Russian "Lustre" oil is heated over a water-bath for an hour to drive off any traces of oils volatile below that temperature.
Alcohol.....	90 per cent.

The gases for the experiments were obtained as nearly pure as was compatible with ordinary manipulative precautions and methods of purification, and the percentage of gas, as well as nature and percentage of impurities ascertained, the absorption figures given in the tables being in each case the amount of pure gas taken up.

The methane used was prepared from methyl iodide and alcohol with the zinc-copper couple, and was purified by passing through U-tubes containing copper zinc moistened with alcohol and concentrated sulphuric acid respectively.

Ethane was prepared from ethyl iodide and alcohol under the same conditions, whilst the ethylene was prepared by the action of heated sulphuric acid on alcohol, the gas being afterwards passed through caustic soda in order to absorb any acid fumes.

The carbon monoxide was made from potassic ferrocyanide and sulphuric acid with the usual precautions, and the oxygen from potassic chlorate. Water was used as the trapping fluid in all the experiments.

In each determination the gas was, after measuring in the endiometer, run into the laboratory vessel and allowed to stand for 10 and 20 minutes respectively quietly over the absorbing fluid, the amount taken up being measured at the end of each period, whilst in a second experiment the absorbent liquid was kept agitated for the same length of time in contact with the gas. The results obtained were as follows:—

Absorbent.	Ethylene.

These experiments show that none of the absorbents used could be employed to separate ethane or other members of the paraffin series from the methane, as the latter gas is freely soluble in all of them, but further experiments showed that in mixtures of ethane and methane contact with paraffin with occasional agitation for from 20 to 30 minutes, removed all ethane and a large proportion of the methane, the remainder of which could be determined by explosion and estimation of the carbon dioxide formed, the volume

absorbed by the paraffin plus the volume of carbon dioxide formed on explosion giving the total volume of saturated hydrocarbons.

Experiments with the unsaturated hydrocarbons also showed that it is not possible by any of the absorbents at present in use to effect a separation.—the idea that the ethylene, &c. can be absorbed by bromine and then benzene by fuming nitric acid, being purely fallacious—any absorption by the nitric acid under these conditions only meaning that some of the mixed unsaturated hydrocarbons had escaped absorption by the small amount of bromine in the bromine water, or else that the fuming nitric acid was attacking the ethane and methane present, which it does on agitation. It is evident from this that the use of 1.56 sp. gr. nitric acid is inadmissible, whilst the use of a solution of bromine in potassic bromide gives undoubtedly the best results, being extremely rapid in its absorption and not attacking any of the other gases likely to be found. These experiments also clearly fix the order in which the absorptions must be made, but only give a general indication of the time necessary to complete the estimation of small quantities of any particular gas in the presence of a large volume of diluents.

This I have attempted to determine by making and analysing mixtures containing known volumes of the various gases, and the general scheme of analysis which has given me the best results is as follows:—

Two carefully calibrated* Stead's apparatuses are taken, one containing mercury as the trapping fluid, the other water, over which all the ordinary absorption analysis may be made, the mercury apparatus being kept for explosion and subsequent estimation of carbon dioxide.

1. Carbon dioxide and sulphuretted hydrogen are first absorbed by the 50 per cent. sodic hydrate solution, 10 minutes' agitation being sufficient to complete the absorption. If a highly purified illuminating gas with less than 1 per cent. of carbon dioxide and no sulphuretted hydrogen is being analysed, this determination may be done over water, but with an experimental carburetted gas which may contain much more, the mercury apparatus must be used.

2. The oxygen is next absorbed by alkaline pyrogallate, 20 minutes being as a rule needed to complete the absorption.

In using the pyrogallate, the solution must not be too freshly made, nor must it have been used more than three or four times, as after a certain proportion of oxygen has been absorbed it begins to give off carbon monoxide. On making up the solution it should be allowed to stand all night before using, and five absorptions are the most for which it should be used.

3. The unsaturated hydrocarbons are now estimated by absorbing with the solution of bromine in potassic bromide, and the action is completed in 15 minutes with gentle agitation.

Bromine vapour is absorbed before measurement by agitation with sodic hydrate.

4. Carbon monoxide is next absorbed by acid cuprous chloride, and the estimation of this gas is the least satisfactory of any, as it is almost impossible to get the last traces of it absorbed. The cuprous chloride must not be used more than twice with gases containing 20 per cent. or upwards of the monoxide, nor more than four times with an ordinary coal-gas. As much as can be absorbed will be taken up in 20 to 30 minutes with agitation.

5. The saturated hydrocarbons are now partly absorbed by paraffin oil, 30 minutes being required to ensure complete removal of the last traces of ethane, butane, &c., and a portion of the remaining gas is now run into the mercury endiometer, measured, mixed with excess of oxygen, and exploded, the carbon dioxide formed being then absorbed over sodic hydrate, giving the volume of methane unabsorbed by the paraffin. In exploding, attention should be paid to

* This is a most important point to attend to as the tubes are often very unequal, especially near the top, the first five divisions sometimes not being equal to more than three of the lower ones.

the taps of the apparatus, which should be secured by an india-rubber band, as the shock sometimes loosens the cock and causes a leakage.

It is usual in exploding to either dilute or else to attenuate the mixture by reducing the pressure before passing the spark in order to prevent the force of the explosion being too great for the endiometer. If, however, this is carried too far incomplete combustion takes place and a certain proportion of the hydrogen and marsh-gas escape being burnt, and one great advantage of absorbing the higher members of the paraffin series before explosion is, that a very slight reduction of pressure makes the explosion perfectly safe and yet ensures complete combustion, whilst the necessity of using a large excess of oxygen being done away with, there is not so much tendency for any of the nitrogen to unite with it.

6. Having now determined the gases soluble in sodic hydrate, the oxygen, unsaturated hydrocarbons, carbon monoxide, and saturated hydrocarbons, it would be quite allowable to absorb excess of oxygen by alkaline pyrogallate and take the residual gas as nitrogen, calculating the hydrogen by difference. It must, however, be borne in mind that in each operation some small error has crept in, and the total of these having to be borne by the residual gas brings out the nitrogen far too high, and it is no unusual thing to see two or three per cent. of nitrogen returned in the analysis of an illuminating gas which in all probability does not contain a quarter that amount.

In order to as far as possible eliminate this error, I now start with a fresh measured volume of the gas, mix it with a large excess of oxygen, and explode over mercury, and then treat the residual gas with strongly alkaline pyrogallate for 20 minutes, keeping it well agitated in contact with the gas. This absorbs both carbon dioxide and excess of oxygen, and an accurate determination of the nitrogen is obtained. The analysis has so far given:—

1. Carbon dioxide and sulphuretted hydrogen.
2. Oxygen.
3. Unsaturated hydrocarbons.
4. Carbon monoxide.
5. Saturated hydrocarbons.
6. Nitrogen.
7. Hydrogen (by difference).

And with ordinary manipulative skill in transferring the gases from the endiometer to the absorption vessels and back again, the results will be fairly accurate, the carbon monoxide, however, being probably from 0.5 to 1.0 per cent. too low, and in consequence the saturated hydrocarbons the same amount too high.

The following example of a test experiment may be taken as a fair average illustration of the results obtained:—

	Gas taken.	Pound.	Time of Absorption.
			Minutes.
Ethylene	17.5	17.5	15
Carbon monoxide ..	30.5	29.7	25
Ethane	17.25	52.8	Paraffin absorption = 30 mins.
Methane	34.8	52.8	
	100.0	100.0	

In order to complete the analysis with an ordinary coal-gas, and to trace the action going on in many forms of carburetted apparatus, it is necessary to be able to estimate the acetylene, sulphuretted hydrogen, and other sulphur compounds which are likely to be present in minute traces and which cannot be determined by any volumetric method of the above character.

In order to do this it is necessary to pass a large volume of the gas to be tested at a very slow rate of flow through various absorbents, and the method which I have found to yield the best results is one proposed by Winkler. The gas is measured by either passing through a delicate meter, or else is measured in aspirating bottles, and is made to pass

through two Vollhard's absorbing bottles containing 20 cc. of concentrated ammoniacal silver nitrate solution. This absorbs the acetylene with formation and precipitation of silver acetylide, and also absorbs the sulphuretted hydrogen with precipitation of silver sulphide, two absorbing vessels being quite sufficient to prevent any traces of these gases escaping absorption. The contents of the two bottles are filtered and carefully washed with water, and the precipitate of silver sulphide and acetylide is then treated on the filter very cautiously with dilute hydrochloric acid until all action ceases. Acetylene is given off and the precipitate then consists of a mixture of chloride and sulphide of silver. This after washing is digested with dilute ammonia and the ammoniacal solution after filtration is then treated with nitric acid to precipitate the chloride, which is then weighed in the usual manner, 1 gm. of silver chloride corresponding to 0.09068 gm. or 78.0314 cc. of acetylene. Winkler claims that the portion of the precipitate left unacted upon by the dilute hydrochloric acid and undissolved by the ammonia is sulphide of silver, and contains no metallic silver, so that the precipitate can be converted into silver by ignition in a current of hydrogen and the sulphuretted hydrogen calculated from the weight obtained. In my experience, however, this is not so, as all illuminating gases contain carbon monoxide which undoubtedly exercises a strong reducing action upon the silver solution, the rate of reduction depending upon the percentage of carbon monoxide.

In order to conclusively settle this point I made a mixture of the character of ordinary coal-gas and added known volumes of carbon monoxide, and tested these for reducing power by causing them to bubble slowly through the absorption vessels and noticing how long it was before metallic silver began to precipitate:—

Percentage of Carbon Monoxide in Mixture.	Length of time necessary to start visible Reduction.
Per Cent.	
2	No action even after 5 hours.
5	1 hour and five minutes.
10	Nineteen minutes.
20	Fifteen minutes.
50	Ten minutes.

It is evident, therefore, that if there is more than a mere trace of carbon monoxide in the gas the sulphur must be estimated by complete oxidation and estimation as sulphate. In order to estimate the sulphur compounds other than sulphuretted hydrogen, the gas after leaving the second absorption flask is passed over platinised asbestos or pumice heated to about 400 °C. in a small-hore combustion tube, which in the presence of hydrogen converts the sulphur compounds into sulphuretted hydrogen, which can be absorbed by a lead solution and estimated in the usual way.

Two absorption flasks for the acetylene and sulphuretted hydrogen are sufficient, as in test experiments with known mixtures it was found that 5 per cent. of acetylene taken rarely came out at less than 4.83 per cent.

By now taking the results of these two sets of analyses we obtain a fairly complete result which can be tabulated as follows, the gas analysed being a sample of South Metropolitan gas:—

I. Carbon dioxide.....	0.79
II. Sulphuretted hydrogen	Nil
III. Bisulphide of carbon.....	0.92
IV. Oxygen.....	0.96
V. Unsaturated hydrocarbons (containing acetylene 0.055).....	4.38
VI. Carbon monoxide.....	2.63
VII. Saturated hydrocarbons.....	33.99
VIII. Hydrogen.....	57.08
IX. Nitrogen.....	0.15

At present I can find no reliable method for the separate estimation of the various hydrocarbons present in illuminating gases, and until this can be done, gas analysis cannot be

of its full value in helping to clear up many points which are still difficulties in the complicated question of carburetted gases. I hope, however, that the work I have brought before you will be a help to others who, like myself, have had to take up this subject, as although such a method as I have described leaves much to be desired, still it correctly gives the salient points of importance to the gas manufacturer and consumer.

Two such analyses can, with good management, be made in a day, so that the amount of time expended is not prohibitive, and I cannot help thinking that if some of those gentlemen who claim to be able to make an analysis of an illuminating gas in a couple of hours were to check their methods on known mixtures they would be considerably startled at the results.

In conclusion, I wish to thank my assistant, Mr. J. A. Foster, for the aid he has given me in working out some of the details of this paper.

DISCUSSION.

Mr. A. E. FLETCHER said that the thanks of the members were due to Professor Lewes for his admirable paper elucidating the methods of analysing complicated gases containing the heavy carbon compounds. The complications which the author had described had been found by many before him; but it was not everyone who had, like him, gone into the subject so thoroughly and carefully as to distinguish the reasons for their occurrence. He would not stay to discuss the details of the paper at that moment, but he should read it in the Journal with great pleasure. Much instruction would be derived from a study of the facts so ably brought forward.

Mr. T. S. LACEY feared that not many members were present who had made a study of coal-gas analysis; but if any such were there he hoped that they would do as much as possible to elucidate the question before the meeting. There could be no doubt that all who had had experience of this difficult branch of analysis would feel deeply indebted to the author for the work which he had brought before them. The text-books treated the subject as if it were of a very simple nature, passing very lightly over all its difficulties. One would imagine on reading the descriptions of the processes therein given that they could be carried out with marvellous accuracy, percentages of the various gases being given up to many decimal places. But when one came to do the work, especially if he attempted to repeat his experiments under varying conditions, he would find that serious discrepancies cropped up which had to be dealt with; and it was the discovery of the causes of those discrepancies which was the most important part of the work. One of the most difficult things was to decide how much oxygen should be mixed with any particular gas in order to cause its perfect combustion without acting on any of the nitrogen in the mixture. If Professor Lewes could give them some further information on that point, on the nature of the residual gases, the pressure employed, and the amount of oxygen used under different circumstances, it would be very valuable. This was a most important point, and he felt sure that the author's experiments had been so complete that he could give further information in relation to it. It was a source of difficulty with everyone who had experience of the subject. If too large an excess, or too small an excess, of oxygen were employed, the results obtained were vastly different. At the same time there was one possible mixture which would give tolerably accurate results. It was always difficult to tell whether complete combustion had been obtained or not; and one might make an analysis and get very inaccurate figures without knowing it, until the work was carefully repeated. As to the question of absorbing the gases of the ethylene series, it was well known that in using sulphuric acid one did not absorb any of the paraffins; and as they might constitute an important part of the mixture, and affect the illuminating power of the gas, he did not consider that a correct idea could be arrived at by simply absorbing the olefines by sulphuric acid. The figures which the author had given them would be of great use to those who had to

perform analyses of gases; and if he would give some further details of his processes the paper would constitute a most valuable addition to the very limited amount of information at present obtainable on the subject. There was one further question which he would like to put, viz., could the process be used with mercury?

Professor V. B. LEWES replied that all the observations referred to by him had been made over water. He used the mercury eudiometer only for estimating the carbon dioxide, and for explosion. It was impossible in rapid working to use either cuprous or bromide solution without soiling the solution.

Mr. W. FOSTER had commenced his acquaintance with the difficulties of gas analysis some six years ago, and had found it refreshing to hear the author recount his experiences of the troubles which everyone had to encounter in dealing with the subject. He now found that he had a companion in his troubles, and he thought that it was extremely likely that they would be in company for a long time to come. He himself had gone through all the difficulties described by Professor Lewes and a good many more, and he thought that when the author had been at work for a year or two longer he would find it necessary to modify some of his assertions. Even in the case of so simple a reagent as pyrogallie acid, for the absorption of free oxygen, the text-books on gas analysis made no mention of the production of small quantities of carbonic oxide. And it was just that point which he believed had been mentioned by Bunsen, Russell, and probably others, that rendered it unfit to be used in the process for the removal of oxygen, except in cases where the quantity was relatively small. When he found a member presenting a report showing 11 per cent. of nitrogen in an analysis of a gas naturally containing but a mere trace, he could not but believe that he had used pyrogallie acid for the removal of excess of oxygen after an explosion. In such a case the carbonic oxide would show itself and be called free nitrogen. That difficulty alone had given him months of labour in the past. He had spent a considerable time in connexion with the endeavour to get rid of the use of Nordhausen acid as an absorbent of the heavy hydrocarbons. Recently he had made investigations of the gases from various shale distilling works in Scotland, and that had led him to go thoroughly into the question of the reliability of different reagents as absorbents. He had come to the conclusion that it was possible to replace Nordhausen acid by a reagent which was not so severe in its action on the mercury. A saturated solution of cuprous chloride in hydrochloric acid was used in the absorption of carbonic oxide. A gas rich in carbonic oxide after two liberal treatments would still show a further very slight diminution in volume on a third treatment. That was his experience after considerable experiment; and the inference he drew from his own work was distinctly in opposition to the recommendations of one well-known chemist. In other words the last traces of carbonic oxide were removed by cuprous chloride with difficulty. The fouling of the mercury by this reagent was notorious. No substitute had been proposed. Sulphuretted hydrogen could be got rid of by means of a number of absorbents. He had tried copper salts, lead salts, and mercury salts, and had come to the conclusion that mercuric chloride was very good and did not interfere with the mercury in use. He did not believe in water or saline solutions as the containing liquid. After getting rid of the sulphuretted hydrogen, one could get rid of carbonic acid by means of potash. He mentioned this because the author had referred to certain analyses which had been put forward, and he rather suspected that he was the author of them.

Professor LEWES: No, you are one of the few gentlemen who have not fallen into that error.

Mr. FOSTER continuing, said he was glad to hear that. He gave these explanations because, although they might be tedious, he felt that he was as it were on his "native heath," and had a right to speak. He had dealt with

sulphuretted hydrogen and carbon dioxide. Small quantities of oxygen could be safely removed by alkaline pyrogallate. Next came Nordhausen acid, which might probably be modified, as it was a nasty reagent, though a useful one. That gave one the volume of the heavy hydrocarbons. If, then, one knew the amount of oxygen needed for the heavy hydrocarbons and the carbonic acid which they produced, one had the means of working out an average molecular formula; and he did not think that gas analysis would ever get much beyond that. The volume of heavy hydrocarbons in ordinary coal-gas was between 5 and 7 per cent., and to hope to differentiate those bodies from small quantities of 100 cc. or so of original gas was, he would not say absurd, but impossible.

With reference to the removal of carbon monoxide, he was glad that the author had laid so much stress on that point, as it was one of the most objectionable constituents. It was a difficult gas to get rid of, and he did not know of anything better for the purpose than the acid saturated cuprous chloride. Then there were the paraffins (marsh-gas), free hydrogen, and free nitrogen. The determination

of these was a point on which the author and himself were not in agreement. Professor Lewes was hopeful of devising a process whereby he could remove the various hydrocarbons of the paraffin series. His own method, however, had been to get at a measure of the free hydrogen in the mixture. He was glad that the author had put that matter before them so pointedly. Getting the free nitrogen was an easy matter; and if one could only estimate the free hydrogen by burning with palladium asbestos they would have an excellent process, and would then be able to get the amount of oxygen needed for the whole of the paraffins. He did not like to speak too definitely on the matter; he was, however, going over the work of Bunsen and others, and was rather hopeful. He was very hopeful at one time; but when one came to experiment with gases from many and diverse sources it was necessary to proceed carefully and not generalise in a hurry. If one could burn the free hydrogen, then ascertain the volume of the residual gas, and then explode it, one would have the very essence of a practicable process. He reserved the results of his experiments for the present, because he was not yet sure that they were to be trusted. If one gave a wrong representation to the free hydrogen in the volume, the paraffins would of course be out also in the inverse direction. Having got rid of every trace of carbon monoxide from his paraffin mixture, he was hopeful of getting rid of the free hydrogen without much, if any, combustion of the paraffins. Already the process had proved very valuable. There were many other points that he would have wished to refer to of a small order in themselves, but most important in connexion with the subject under discussion. Thanks to Mr. Lennox, who had made him a special form of eudiometer to which type he had adhered ever since, he had been enabled to get over some of his earliest difficulties. He now made them for himself with certain modifications on the original form, which he believed was introduced by Professor Dittmar. To calibrate an instrument and then use it as an explosion vessel was, he thought, wrong in practice, and therefore he always employed a separate vessel. He had also devised a special absorption apparatus, which those who had occasion to make gas analyses would, he thought, find very handy though probably it might not be novel. It enabled one to remove the gas sharply from the liquid absorbent. A modification of the absorption vessel had also been used. A funnel and stop-cock enabled one to remove the absorbent or introduce it. He used separate apparatus of this kind for potash, for cuprous chloride, and for the various other reagents in turn. These absorption apparatus had been made for him by Messrs. C. E. Muller and Co., of Charlotte Street, W.C.

Professor V. B. Lewis, in reply, said that he was sorry that he had not elicited more discussion, but one or two good points had been brought forward, the honour of which rested, he thought, with Mr. Lacey. He had referred to one of the most important points possible, namely, the conditions under which explosion best takes place, and how those conditions were to be modified so as to avoid any oxidation of nitrogen at the same time as the explosion. He thought that Mr. Lacey would agree with him that the absorption of the higher paraffins was a distinct step in that direction. If one absorbed the higher paraffins, and thus had only the marsh-gas to deal with, then, knowing approximately the proportion of that body, one could put in a slight excess only of the oxygen required to combine with it, and in that way get fairly concordant results. That was one of the advantages of the primary paraffin absorption. He felt relieved to find that Mr. Foster had met with the same difficulties that had occurred to him. With regard to Mr. Foster's remarks on carbon and hydrogen densities, he knew that Mr. Foster had been guilty of such things on several, indeed many, occasions; and he had already confessed that he had not much respect for his own carbon and hydrogen densities or anybody else's. But if Mr. Foster could differentiate between the higher members of the saturated hydrocarbons, he would confer a greater benefit on gas analysis than any that he had yet conferred, and he hoped that he would go on working in the direction he had indicated, and give them

the benefit of the process. He himself had not succeeded in doing so, and he had pointed out that, as far as his experience went, it could not be done by absorbents, and he very much doubted if any combustion process could be utilised for the purpose.

THE ANALYSIS OF THE PRODUCTS OF INCOMPLETE COMBUSTION.

BY VIVIAN B. LEWES.

THE methods of analysis which serve to separate and estimate the constituents in an ordinary gas fall altogether to detect the presence of minute traces of such gases as methane, hydrogen, acetylene, and carbon monoxide when mixed with large volumes of inert gases such as nitrogen; and, moreover, as these four gases offer great difficulties of separate estimation by any combustion processes at present in use, the determination of them in the products of incomplete combustion escaping from flames which are used for heating purposes, has up to now proved unsuccessful.

At the last meeting of the British Association at Leeds, Mr. W. Thomson read a paper upon the products of incomplete combustion of gases given off from gas stoves, and attempted to separately determine the quantity of carbon monoxide and hydrocarbons found in the flue gases, but, like most other observers who have attempted to do this, he found it so beset with difficulties that he abandoned the attempt and contented himself with determining the total quantities of carbon and hydrogen escaping in an unburnt condition, experiments which showed that the combustion of gas in stoves for heating purposes is far less complete than had been imagined, but, unfortunately, they gave no idea as to whether the carbon and hydrogen were present with the products of combustion simply as such harmless constituents of the gas as methane and hydrogen, or whether they were there as the highly poisonous products of incomplete combustion, acetylene and carbon monoxide.

For some time past I have been trying to utilise the well-known property which finely-divided palladium has of causing the oxidation of hydrogen, but not of methane, when a mixture of these two gases with air are passed over it, as a separation between them, the carbon monoxide present, however, would have been a difficulty in the way of doing this had not experiments shown that carbon monoxide is oxidised to the dioxide under the same conditions as bring about the oxidation of hydrogen when passed over the heated palladium asbestos.

In the use of palladium asbestos for the combustion of hydrogen, it has always been customary to lead the gas with an excess of air or oxygen backwards and forwards several times over the surface of a single fibre of the impregnated material in a fine tube, but this would be practically of no use in the analysis of gases from incomplete combustion where the products of combustion would have to be led in a continuous stream through a series of combustion tubes and absorption vessels, and it was therefore necessary to try by experiment whether, during the slow passage of a large volume of mixed gases through a heated tube containing a large quantity of palladium asbestos, a satisfactory combustion of the carbon monoxide and hydrogen could be obtained without at the same time interfering with the methane present, as, if so, the acetylene can be absorbed first of all in the usual way by ammoniacal silver nitrate, the carbon monoxide and hydrogen estimated by combustion in contact with palladium asbestos, and the methane determined by a further combustion in contact with platinised pumice.

The palladium asbestos for these experiments was prepared by dissolving about 1 grm. of palladium in aqua regia, and evaporating the solution almost to dryness so as to get rid of excess of acid. About 1 grm. of asbestos fibre was then introduced into the concentrated palladium solution, and when it had soaked up most of the liquid, a few cc. of

a concentrated solution of sodic formate and enough sodic carbonate to make the solution strongly alkaline were added.

In this way the palladium is precipitated between the fibres of the asbestos, and, after drying and igniting, the residual salts are dissolved out by washing with boiling distilled water, and, after being dried, the palladium asbestos is ready for use.

The platinised pumice stone was made in the ordinary way by taking ignited pumice stone, broken into small pieces, and soaking in a concentrated solution of platonic chloride, the pumice being afterwards dried and ignited to drive off the chlorine.

Methane, carbon monoxide, and hydrogen were prepared as in the experiments described in the previous paper, and the percentage of true gas in each having been carefully determined, a mixture was made containing—

	Per Cent.
Hydrogen	3.60
Air	71.31
Oxygen	20.00
Methane	1.30
Carbon monoxide	0.79
	<hr/> 100.00

This mixture was confined in a carefully graduated glass bell jar over water, and after being carefully freed from any trace of carbon dioxide by passage through caustic potash and dried by calcium chloride, it was then passed through a small combustion tube 10 in. in length, containing the palladium asbestos, heated by three spirit lamps placed 3 in. below it, the carbon dioxide and water so produced being collected in a series of absorption tubes, giving the carbon monoxide and hydrogen present in the gas, whilst the residual gas passed on over the platinised pumice, heated to a high temperature by a series of Bunsen burners, the products of combustion being collected in another set of absorption tubes. The results, however, obtained in this way were not very satisfactory, three analyses of the mixture giving the following results:—

	L.	II.	III.	Taken.
Hydrogen	3.00	3.84	3.28	3.60
Methane	4.32	4.40	4.33	4.30
Carbon monoxide	0.30	Nil	0.58	0.79

In these experiments the methane and hydrogen agree fairly well, but the carbon monoxide results are unsatisfactory. Other experiments were then tried, in which the distance of the spirit-lamp flames from the tube containing the palladium asbestos were varied, and the results obtained showed that up to a certain degree increase of temperature gave an increase in the accuracy of the results, but when the heat was too strong traces of methane were decomposed, and made the carbon monoxide and hydrogen results too high. It was evident, therefore, that in order to obtain a reliable process of analysis means must be taken to accurately regulate the heating of the palladium asbestos, and this was done by bending the tube containing it into a V shape, and heating it in a bath of melted paraffin wax. After many experiments at various temperatures it was found that 200° to 220° C. gave the best results; as for example:—

	Taken.	Found.
Hydrogen	1.83	1.86
Methane	1.71	1.76
Carbon monoxide	1.50	1.47

Having thus got a reliable method for analysing small traces of these gases, the process was employed for determining the composition of the gases escaping into the

atmosphere when the flame of an atmospheric burner is brought into contact with the bottom of a vessel which is kept cool by water between the temperatures of 0 °C. and 100 °C.

No flame is in contact with the substance which it heats unless the latter be at the same temperature as the flame itself, and this is due to the fact that the substance being heated, by conducting away the heat from the flame, practically plays the same part as the gauze of a safety-lamp, and so cools down the flame that the ignition point of the gas is not reached in the immediate neighbourhood of the heated surface, and the flame is thus extinguished for a certain distance from the bottom of the vessel; these extinguished flame gases then creep along the cooling surface and finally escape into the air.

In making any experiments on the composition of these checked products of combustion, it is evident that the smaller the admixture of air with the products of combustion the better, as the difficulties of analysis increase with dilution. After many attempts to devise a form of apparatus which would allow the products of combustion to be collected, without at the same time giving too great an admixture of air or interfering with the process of combustion going on, I at length came to the conclusion that the best form of apparatus to use was a tin-lined copper pot, filled with a false bottom which gave a space of 1 in. between the two bottoms. A circular aperture $2\frac{1}{2}$ in. in diameter was then cut in the centre of the false bottom, whilst a small exit tube one-eighth of an inch in diameter was fitted into the side of this lower compartment. On now putting a known volume of water at 0 °C. into the vessel and placing a Bunsen burner with a flame of carefully regulated size below it, so as to allow the flame to pass through the hole in the false bottom and impinge upon the bottom of the vessel itself, it was possible to draw off the products of combustion from the exit tube at the side without having a larger volume of air than necessary mixed with it. The gases on leaving this tube were first passed through carefully prepared fused calcic chloride, which had been previously treated with carbon dioxide to prevent any free alkali being present, and the increase in weight of these tubes gave the water vapour produced by the combustion. The gas then passed on through tubes containing caustic potash to absorb carbon dioxide, and then through a tube in which a sample could be taken for determination of the oxygen, whilst the acetylene was next estimated by passing the gas through two absorption flasks containing ammoniacal silver nitrate,* an absorption flask containing sulphuric acid to take up any ammonia, and a drying tube. Next to these came the palladium-asbestos tube heated to 220 °C. in a paraffin bath and the L tubes containing the calcic chloride and caustic potash for estimating the water vapour and carbon dioxide formed, whilst again beyond these came the platinised pumice heated by a flat flame burner nearly to the softening point of the combustion tube, the water and

carbon dioxide formed by the combustion of the methane being estimated in the usual way; beyond these tubes came a trap tube of calcic chloride, and finally aspirating vessels in which the volume of gas sucked through could be measured, and after correcting for temperature and pressure, the volume of gas absorbed in the experiment could be added, giving the total volume of products of combustion drawn through. An experiment tried with this apparatus on a mixture of known composition showed that an excess of oxygen must be mixed with the products of combustion in order to give satisfactory results, with such low forms of combustion as those taking place in the palladium-asbestos tube, and a carefully measured quantity of pure oxygen was therefore made to flow in at a steady rate to the second acetylene absorption bottle, so as to mingle with the products of combustion before passing over the palladium-asbestos, the gas being kept in a carefully graduated glass gasometer, so that the volume used could be subtracted from the total volume of gases after correcting for the amount used in the various combustions; in this way the products given off when the vessel was heated at a point half an inch above the inner zone of the flame, and also at the tip of the flame, were determined with the following results:—

GASES ESCAPING DURING CHECKED COMBUSTION.

	Bunsen Flame.		Luminous Flame.	
	Inner.	Outer.	Inner.	Outer.
Nitrogen	75.75	79.17	77.52	69.41
Water vapour...	13.47	14.29	11.80	13.24
Carbon dioxide .	2.39	5.13	4.93	8.38
Carbon monoxide	3.69	Nil	2.45	2.58
Marsh-gas	0.51	0.31	0.25	0.39
Acetylene.....	0.04	Nil	0.27	Nil
Hydrogen.....	3.55	0.17	2.08	Nil
	100.00	..	100.00	100.00

These figures are of considerable interest, as they show that the extreme tip of an atmospheric burner is the only portion of a flame which can be utilised for heating substances cooler than itself without giving rise to deleterious products of incomplete combustion, these results being also corroborated by analysing the gases escaping unburnt from the outer zone of a luminous flame and an atmospheric burner flame respectively.

A. Tin-lined copper vessel with false bottom containing water to be heated.

B. Tubes for absorption of the carbon dioxide and water vapour in products of combustion.

C. Collecting tube for sample of mixed gases to be analysed for oxygen.

D, E. Absorption vessels for estimation of acetylene.

F. Graduated glass gasometer for supplying excess of oxygen for combustions.

G. Absorption vessel with acid to take up any ammonia carried from D, E.

H. Drying tube.

I. Paraffin bath with tube containing palladium asbestos.

J. Tubes for absorption of the carbon dioxide and water vapour from combustion of hydrogen and carbon monoxide.

K. Combustion tube containing platinised pumice.

L. Tubes for the absorption of carbon dioxide and water vapour from combustion of the methane.

M. Trap tube of chloride of calcium in connexion with aspirator.

* If, after estimation of the acetylene of silver, any metallic silver is left, it shows that the percentage of carbon monoxide in the gas has been large enough to bring about reduction, and the silver must be estimated and carbon monoxide so used calculated and added to that found by combustion.

GASES ESCAPING FROM THE OUTER ZONE OF FLAME.

	Luminous.	Bunsen.
Nitrogen	76.612	80.242
Water vapour.....	14.702	13.345
Carbon dioxide.....	2.201	4.966
Carbon monoxide	1.189	0.006
Oxygen	2.300	1.430
Marsh-gas	0.072	0.003
Hydrogen	2.888	0.008
Acetylene.....	0.036	Nil
	100.000	100.000

Which shows that the air mixed with coal-gas in the atmospheric burner produces a far more complete combustion than in the case of a luminous flame, where the air, mixing with the partially-burnt coal-gas, so dilutes it and cools it down at the edge of the flame, that large quantities of even the inflammable hydrogen escapes unburnt. In the analyses of the products of incomplete combustion, the large proportion of carbon monoxide in the outer tip of the luminous flame is due to the carbon dioxide being reduced by the deposit of red-hot carbon on the bottom of the vessel to the lower oxide, and these results are in very fair accord with what one would have expected from the experiments of Dr. Blochmann upon the composition of the gases present in various parts of the Bunsen flame, the result he obtained by withdrawing gas at various heights above the burner being as follows:—

Height above Tube.	In Tube.	1 Inch.	2 Inch.	3 Inch.	Complete Combustion.
Air with 100 vols. of gas	253.9	284.7	284.5	484.3	608.8
Hydrogen.....	48.6	36.4	17.7	16.1	Nil
Marsh-gas	39.0	40.1	28.0	5.7	Nil

These figures also tending to show that the flame of an atmospheric burner cannot be used for any heating purposes without the escape of deleterious products except at the extreme tip where combustion is completed, and that, therefore, in all forms of gas-heating apparatus it is the hot products of combustion and not the flame itself which should be employed as the source of heat, unless through ventilation can be obtained and none of the gases from the checked combustion allowed to find their way into the atmosphere of the room. In conclusion, I wish to thank my assistants, Messrs. J. A. Foster and Warden, for the help they have given me in the work entailed in this paper.

DISCUSSION.

Dr. L. T. THORNE felt that he was only expressing the sense of the meeting when he said that they were grateful to Professor Lewes for the interesting experiences which he had communicated in the paper he had just read. The subject was of immense importance, and perhaps more so at the present time than it had ever been before, when the

use of gas for heating purposes was being so much extended, and, if one could judge by appearances, would become still more extended in the near future. The whole question of incomplete combustion was one of the most serious points in the use of gas as a heating agent. He supposed that there were very few heating stoves at present in use that were perfectly innocent in that matter. In fact, a great number of the stoves that were sold for heating purposes were simply abominable in that respect; and the prejudice against using gas for heating purposes was very largely due to the fact that the question of incomplete combustion had either been ignored or only insufficiently recognised. Manufacturers of stoves had taken little or no account of the conditions that should be carried out to produce a stove free from the danger of contamination of the atmosphere of the room in which it was used. Professor Lewes's results were, he thought, most interesting, and the apparatus employed seemed to him to be not only very neat, but exceedingly well fitted for the work which he had carried out. He had obtained analyses of the products of combustion at the surfaces of flames in a different manner from that usually followed, and had thus been able to differentiate the products at the various parts of the flame in a way which would prove to be of the greatest importance. Personally, he felt that this was one of the most important papers presented to the Section.

Mr. BERTRAM BLOUNT, while fully endorsing all that Dr. Thorne had said as to the sins of the average gas stove, would point out that Professor Lewes had not given them any data on which to condemn it. His experiments dealt with the incomplete combustion of gas in contact with surfaces at a low temperature. But gas stoves that had any right to the name depended for their efficiency upon the incandescence of refractory substances, the gas, after that incandescence had been brought about, playing upon the surfaces of the refractory body, its combustion being thereby probably rendered more complete. If the author could give them analyses of gases drawn from the neighbourhood of the flames of a well-made gas stove, or any other form of heating apparatus; if he could give them analyses of the gases given off at the point where the Bunsen flame played upon a refractory substance, then they would have some data for saying that gas stoves did or did not incompletely burn the gas that they used. And in addition, the author's experiments were open to this objection. In order to collect the gases, he had had recourse to the device of a false bottom, and he (Mr. Blount) did not know that a better plan could have been adopted. But it appeared to him that even with the careful regulation which the author had exercised, and the necessity for which he had so strongly insisted upon, there must be some checking of the combustion, and the Bunsen flame would in consequence show worse than if it had been allowed to burn freely, without any such restraining influence.

Mr. T. S. LACEY could confirm Mr. Blount's remarks as to the great importance of the method in which the products of combustion were collected. If the flame were at all affected by the casing, as he certainly thought it must be, inasmuch as the amount of air passing in under ordinary conditions would be limited by it, then of course the results would not be the same as would be got if the gas were burnt in the ordinary way. The same objection applied to some extent to the difficulty of collecting gases from any flame without in some way or other interfering with the normal action of that flame. Considering how great those difficulties were, it appeared to him that the author had exercised every care in trying to avoid all such errors as were avoidable. He had shown them a method by which they could analyse those gases; and although he thought it probable that the normal action of the flames had been interfered with by the method of collecting the products of combustion, still that in no way detracted from the value of the paper as indicating to others researches which they could continue in any way they might think proper. Professor Lewes's method could be easily applied by anyone having a reasonable knowledge of chemistry; and its application would give an impetus to these investigations, and so fuller knowledge of the subject would result. It would have been more satisfactory to have

taken the actual products of combustion from, say, a gas stove (of which he had not a very high opinion) or from a gas burner, as they went into the air. But as the author had said, the immense volume of air made the difficulties of that method of working almost insuperable. Nevertheless he hoped that eventually they would be able to collect the products of combustion without interfering with the action of the flame and in such a way that they would be in the condition in which they were given off under ordinary circumstances. It was startling to be told that such gases as hydrogen and marsh-gas could come off without combustion, passing through a strongly heated flame, where one would imagine that they would always be in contact with an excess of oxygen. The whole paper was full of food for reflection, and would well repay the careful study of the members, who were much indebted to the author for the immense pains which he had bestowed on the researches which it described.

Mr. W. FOSTER said that the whole value of a communication such as this was that it directed attention to a most pertinent question, the use of gas for heating purposes. Briefly stated, the condition of affairs was this. Whether oxygen was present in excess or not, a flame in the course of its combustion was surrounded with something at a temperature below the combustion temperature. That was the essence of the question. Whether it was a kettle, or the cold cylinder of a gas engine, it mattered little; the same effect resulted. The temperature of combustion was lowered; and the coefficients of chemical affinity of the different factors being different, the one which was the greatest, viz., the hydrogen, was consumed first and the other factors followed according to the nature of the mixture. This subject came under the notice of Mr. Dibdin and himself some years ago, during an exhibition at the Crystal Palace; and it was a matter of regret to both of them that they had not had an opportunity of fully studying the conditions of the combustion products in various heating apparatus, for there were appliances there on that occasion which had not been brought together since. The nature of the mixtures of course determined the character of the effluent gases; the more hydrogen in the mixture the less would be the carbonic acid and carbonic oxide produced. That led him to the question of the experiments made. The author confirmed him in the hope that the employment of palladium asbestos would give him the means of solving all his difficulties in connexion with the estimation of free hydrogen in mixtures of paraffins. He had not yet subjected palladium asbestos to treatment with mixtures of known volumes of paraffins, but he found that the author used it in the tube to burn his marsh-gas. If his hopes were realised, and this proved a practicable means of ascertaining the amount of free hydrogen, one of the greatest difficulties of gas analysis was solved, for it would enable the analyst to know the quantity of paraffins present. With reference to combustion products and their character generally, he might relate an anecdote. Not many weeks ago he was in the presence of a gentleman holding an official position in the gas industry. He asked him what he was heating the room with. "A sanitary stove" was the reply. "But where is the flue?" he inquired. The reply was: "Don't you know? It is a sanitary stove. It has water underneath, which absorbs all the products of combustion." "But what about the carbonic acid?" "My dear sir," said his friend, in the greatest surprise, "that is absorbed along with the water." That, continued Mr. Foster, being the position of a gentleman who was enlightening the British public, it was evident that we all did not view combustion products in the same light; and he feared therefore that such facts as had been brought before them by Professor Lewes would be very differently received by his hearers and readers.

Dr. C. R. ALDER WRIGHT wished to call attention to one point. Among the various forms of gas stoves made for household purposes were some wherein the products of combustion came into contact with strips or wires of iron instead of lumps of fireclay or asbestos fibres. In such cases the iron became in time coated with a film of oxide. He had not carried out many observations on the subject,

but such few as he had made led him to believe that a much more perfect combustion was obtained under those circumstances than when the flame was made to play upon clay or such like bodies. The improvement might perhaps be attributed to a "catalytic" or surface action of the oxide of iron, analogous to that of the platinised asbestos in the case before them. He would like also to ask, in reference to the column of figures which appeared to the left of the author (see Table, p. 114), what had become of the oxygen which was associated with the nitrogen in the air which was used to burn the gas. In the first three columns they had from 75 to 79 parts of nitrogen; but the water vapour and carbon dioxide, &c. present did not contain the amount of oxygen that ought to have been present associated therewith. It looked as if more oxygen had gone to one part of the flame, and less to another; but there was doubtless some other explanation.

Professor V. B. LEWES, in reply, said that he had started with a paper on gas analysis, and the discussion, after wandering through the groves of gas-stove manufacture, had come back to the subject in an able question by Dr. Wright on a point which he ought to have explained in his paper. He would answer that question first. In the diagram referred to (see Table, p. 114) the oxygen was estimated from the amount taken in the tube, and the amount of nitrogen belonging to that oxygen as air was deducted, so as to give the products of combustion without mixture with air. The proposition of heating iron coated with magnetic oxide with the flame appeared to him to be reasonable, but he had had no opportunity of judging of it yet. In opening the discussion, Dr. Thorne had treated him very kindly; but he could not help thinking that he had dealt somewhat harshly by gas-stove manufacturers. There were several points to be considered in reference to the manufacture of gas stoves. The gas-stove maker would no doubt like to be a public benefactor if he could; but he had at the same time to make his living. The public expected him to give them a stove which would heat a room to a nice high, stuffy, comfortable temperature in a short time; and the maker found himself obliged to produce a stove which would fulfil that condition. It was of no consequence to him whether his customer got a headache or not. In order to have a gas stove which would give off harmless products of combustion, one must use only the extreme tip of the Bunsen burner; and if one asked a maker to make a stove on that principle, he would simply laugh at the idea. To secure rapid heating, the body to be heated must be well down into the flame, and the natural consequence was a crop of noxious products given off into the room where people did not know better than to use such stoves. Not a single stove was made in which the products could be allowed to escape. If people were to use gas stoves satisfactorily they must have absolute ventilation, and lead away all the products of combustion, by pipes or otherwise. Mr. Blount had said that he had not given any analyses of the heating effect upon flames of refractory materials. He would remind him, however, that he had not been talking about the products of incomplete combustion themselves, but about their analysis. But, in fact, it did not much matter whether one heated asbestos or any other material to the point of ignition. In every case products of incomplete combustion were given off, though to a different extent, the percentage of products falling as the temperature rose, but never ceasing entirely. There was no stove existing which he would use and allow the products to escape into the room. Mr. Lacey had made an admirable remark as to the limitation of combustion which must take place in such a vessel as he had shown. But he had pointed out in the paper that that difficulty was strongly in his mind. Nevertheless, if Mr. Lacey would consider the matter, he would see that the products were not increased to such an extent as might at first sight appear. If one took a flat-bottomed saucepan without a false bottom, and heated it with a Bunsen flame, one would have the products of checked combustion making a layer between the saucepan and the flame. The products would creep along the bottom of the saucepan, and at no time would they get far enough away from it to undergo combustion. And it would be found that by using a small

flame in the way he had described, so as not to fill up the hole too much and thus check the sucking in of the oxygen, but leaving a free way for it, then the amount of interference with the flame was as small as it could well be. He had tried many methods, but none had so well fulfilled his requirements as the one he had described.

Meeting held on Monday, April 20th, 1891.

MR. THOS. TYRER IN THE CHAIR.

ON THE ADAPTATION OF STONEWARE TO CHEMICAL APPARATUS.

BY W. P. RIX.

INTRODUCTION AND SCOPE OF PAPER.

It may possibly seem that the subject I have to bring before you is only cognate to the inquiries and researches which usually occupy the attention of this Society, and that it hardly comes within the scope of its transactions.

It must be remembered, however, that many extensive chemical operations are possible only through the important development of stoneware apparatus in later times; and we cannot but conclude that the subject is worthy at least of some slight notice on the part of a society including so large a number of chemical engineers within its ranks.

It was also in the hope that something more than passing interest might result, that I have attempted to-night some description of the methods employed in the production of apparatus in this material.

An experience of over 20 years in connexion with Lambeth Pottery has led me to believe that a considerable number of chemists have but limited knowledge of these details.

The failure of some in obtaining satisfactory results when erecting chemical stoneware plant has sometimes arisen more from a want of appreciating the requisite form of construction than to any inferiority in the material of the apparatus set up.

Success in all constructive arts can only be ensured by studying closely the capabilities of the material to be dealt with. Those who minimise these difficulties by meeting the exigencies of the material, even at the cost of some modification of the original design, will succeed far better than others who, insisting rigidly on some special form or arrangement not inherently superior, add greatly to the risk and expense in producing the apparatus. Undoubtedly there are many notable exceptions, and among those connected with this Society are a large number whose experience has already enabled them to arrive at results that are examples of the highest constructive skill, and to such anything I may have to say will possibly appear somewhat elementary and trifling in its detail.

If, however, the following remarks assist any of my fellow members in realising that it is possible for the potter and the chemical engineer to study the requirements of modern science with more intelligent unity of purpose than hitherto, I shall have accomplished at least one object I had in view.

It is not within the purpose of this paper to deal with the history and progress of the manufacture itself. It is therefore only necessary to remark in passing that although for the last century or more Lambeth has been the seat of the production of salt-glazed stoneware, it is only within the last 50 years that this material has been adopted for chemical apparatus. It is true that salt-glazed wares at one time were largely made in Staffordshire, but in this district, the manufacture having been confined to smaller domestic and ornamental goods, finally died out about 50 years ago, and it was left to the Lambeth potteries to develop and improve the production of strong and heat-resisting wares of larger capacity, and in this way to meet the requirements of the chemical manufacturer. The rapid

extension of scientific research at this time and the astounding expansion of manufactures based upon that research, involved the adoption of chemical processes requiring the use of materials suitable to resist heat and acid and rapid changes of temperature. These processes and the apparatus required soon became more complicated and the dimensions more extended. Glass and porcelain were no longer available with increasing size, and in stoneware the manufacturing chemist found a material well suited to his enlarged operations. About the year 1811 Waters took out a patent for the fabrication of various articles of considerable magnitude by moulding. Some years later the Lambeth potters commenced to give attention to this section, and among others we find the name of Green and Singer engaged in the manufacture. Messrs. Boulton and Watts were perhaps among the earliest to produce such goods and did much to develop the quality. In fact, so much energy and enterprise was expended in discovering suitable materials and enlarging the capacity of the vessels produced on the wheel, that a practically new industry was the result.

Up to the year 1840 about 8 gals. was the limit of size—as it was the limit of power over a single lump of clay upon the potter's wheel. It was a proud achievement when, later on, 100 gals. capacity was reached, and a vessel of 300 gals. for more than a decade remained true to its description as being the largest stoneware vessel in the world. At the present time, care and experience has made it possible, in certain forms, to attain nearly double this capacity.

A. Definition.—Stoneware may be defined as a densely vitreous material, non-absorbent, and impervious to acids and other corrosive compounds. The imperviousness of most other ware is due only to the glaze, the body itself being absorbent. Stoneware, however, is vitrified throughout the entire mass, the glaze being merely added to produce a smooth surface.

B. Body.—To obtain this result, stoneware is formed of a natural clay, extremely plastic, approximating to the composition shown on the diagram (Table A.).

TABLE A.

	1.	2.	3.	4.
Silica	72.23	74.34	74.12	65.49
Alumina	23.25	20.32	20.90	21.28
Ferric oxide	2.54	1.34	0.68	1.23
Calcium oxide	Trace	0.06	0.38	4.72
Magnesium oxide	1.78	3.94	3.92	7.25
Alkalis				

Such are the clays of Devonshire and Dorsetshire, which are highly prized for this purpose.

The vitrification of the body is produced by intense heat, carried to a point beyond which it is impossible to go without causing the entire collapse of the form itself. In this respect stoneware differs from porcelain and china, the vitrification of which is obtained by the addition of fusible materials to the clay.

This fact is most important in the designing of stoneware plant for chemical purposes, and from it largely arises the tendency to warpage and unequal contraction, one of the greatest difficulties with which the stoneware potter has to contend. The temptation is great to avoid extra risk at the sacrifice of a highly impervious body, by reducing the temperature of firing or merely continuing it for a time sufficiently prolonged to vitrify the surface.

It is hardly necessary to point out the importance of this complete vitrification of chemical apparatus, especially when the same vessel is used for various products, and is thus liable to absorb some portion of each into its mass.

It is therefore necessary to obtain a clay which, though maintaining form at high temperature, is sufficiently fusible at that heat to become dense and impervious in body. Nevertheless, it must be plastic and easily formed, even

though it be tempered with sand or other non-plastic material to increase its power of giving up moisture in drying. It must be capable of allowing considerable thickness for strength, and yet not liable to crack either in firing, cooling, or during subsequent use.

The number of clays that will answer all these requirements is very limited, though the compositions produced from them may be greatly varied to give prominence to different qualities needed in the resulting wares.

The composition of such mixtures may be seen on the diagram (Table B).

TABLE B.

	1.	2.
Silica	50.05	60.25
Alumina	25.90	31.08
Iron oxide	1.20	1.12
Lime	0.60	0.30
Alkalis	1.25	1.25

I have also here specimens of bodies possessing these various qualities:—

- Suitable for heating and cooling up to 400°.
- Very impervious, but useful for cold liquids only.
- Capable of resisting heat, yet can be made thick without cracking.
- For boiling acids over fire.
- Suitable only for dry materials heated to low redness.

It is here necessary to remark that these materials are in no sense chemical compounds, and are at best carefully adjusted mixtures, arranged to suit some special use to which the vessels are to be submitted. It must also be remembered that there exists no natural clay absolutely uniform in its composition. Recipes and mixtures have therefore to be constantly readjusted to maintain such uniformity in the mass.

In proportion as the clay is fusible, the resulting vessel will be more vitreous and will suffer greater contraction in firing. This contraction is often irregular from various causes, and the consequent distortion can only be obviated by the admixture of a certain amount of infusible material, such as sand, fireclay, or ground burnt ware. This addition essentially reduces the contraction and density but increases the porosity and the capacity to withstand changes of temperature. The physical condition of the materials themselves and the homogeneous state of the mass before use are, however, of the greatest importance, and require long experience in their adjustment. It has also been long since demonstrated that there is great advantage in allowing the material to lie for a great length of time in its mixed condition before use, the "weathering" process, as it is termed, being often extended over many months or even years. The actual change which takes place during this period has never been clearly ascertained, but the resulting benefit is a well-established fact.

C. *Glaze*. The body of well-burnt stoneware being almost impervious, the glaze is not greatly needed, and in some cases it is an actual hindrance to ready expansion with change of temperature. A glaze is, however, desirable for many purposes, as it presents a smoother surface for cleaning and enables crystals and precipitates to be more easily detached from the surface.

The glaze being more vitreous than the body of the vessel, there is some difficulty in equally adjusting the expansion and contraction of both, and this difficulty is much increased when the layer of glaze is thick. Here is an instance in which the contraction of the two are so unequal that the first application of heat has caused the vessel to rend in all directions.

In the manufacture of earthenware or porcelain it is usual to fire the vessel previously to the glazing process and afterwards to dip into a liquid glaze. The slight porosity of the ware at this stage causes the absorption of some of the water into the body and the consequent deposit of a layer of glazing material on the surface of the vessel.

In the case of stoneware it is usual to omit the first or "bisuit" firing and to glaze the ware in the clay state after it is thoroughly dry—the glaze being adjusted to vitrify at the same temperature as the body. The risks of this operation are, however, considerable, and with the larger vessels almost impossible. It will be seen that the method of salt-glazing has peculiar advantages over all others for this purpose. It is intensely hard, and will scratch almost all other glazes. It is very thin and therefore does not affect the expansion. It is produced automatically during the firing process and thus all risk of injuring the vessel by pouring or dipping of liquid glaze is obviated.

By this plan the vessels when fairly dry are placed in position in the kiln, due care being taken that each stands on a firm basis, yet capable of contraction in the burning equal to the vessel itself. After the kiln is filled, the doorway is bricked up and the firing proceeds very gradually but steadily increasing in temperature and usually extending over several days.

When the greatest heat has been attained and while the whole contents of the kiln are in a glowing condition, common salt is ladled through small apertures provided on the roof of the kiln. The decrepitation causes the salt particles to fly into all parts of the kiln, and these are immediately vaporised by the great heat, being forthwith decomposed. The soda combines with the silica of the surface of the ware, forming a highly vitreous glaze, while chlorine and hydrochloric acid are evolved in a thick white vapour from the outlet of the kiln.

The reaction is as follows:—

By this process, however, the penetration of the vapour to the interior of closed vessels with narrow orifices is only partial, and if glaze is needed it must be added to the interior surface by the liquid process previous to firing.

It is, of course, desirable that this liquid glaze should be as free as possible from ingredients liable to be attacked by acids, &c., and for this reason the ordinary earthenware glazes, which usually contain large quantities of lead and borax, have especially to be avoided.

The composition of glazes suitable for chemical purposes is given on the diagram (Table C).

TABLE C.

	1.	2.
Silica	61.81	65.05
Lime	13.43	13.68
Alumina	10.71	13.14
Alkalis	11.05	7.24
Iron oxide	0.82	0.89

D. *Formation*.—We have now to consider the formation of the ware itself. The methods are various, chiefly the following:—

1. Throwing on the potter's wheel.
2. Moulding in plaster moulds.
3. Machine moulding.
4. Slip moulding.
5. Expression, as in pipes.
6. Dust pressing, as in tiles.
7. Plastic die pressing.

Of these the simplest and most important is that of—

1. *Throwing*.—Notwithstanding its simplicity this is one of the most difficult of operations, and cannot fail to fascinate all who see it for the first time, owing to the rapidity with which the revolving mass of clay receives almost magic changes of form by the deft motion of the potter's hand entirely unaided by tools of any sort. Smaller vessels up to 6 gals. or 8 gals. are formed out of one ball of clay, but in the formation of large vessels, the mass being great has to be manipulated more steadily and with much care, a long experience being needed to obtain

complete uniformity in the tension of every part. Were it not for this care the superincumbent weight would cause the lower portion to collapse. The process is therefore arrested a few hours at various stages to allow the half-formed vessel to stiffen, and a further quantity of clay is afterwards built up and gradually shaped till the whole is complete.

2. Moulding.—It is obvious that only vessels which are cylindrical or at least circular in all their cross sections can be formed on the wheel. For other shapes moulding has to be used. By this plan thin layers of soft clay are carefully laid and pressed into a plaster mould of the desired form. The mould may be in separate parts, which are then closed together and the seams or joints completed by addition of clay at the lines of juncture. Some part of the moisture is absorbed by the porous plaster, thus shrinking and hardening the vessel, and it can in a few hours be removed for drying.

3. Machine Moulding.—A combination of the two processes of moulding and throwing has for some time been introduced in Staffordshire in forming small open vessels. The mould is made to revolve rapidly, and the mass of clay being thrown in, a forming profile mounted on handle or radius is brought downward into the mould. This forces the clay up and against the sides giving it the required thickness. (See Fig. 1.)

Fig. 1.

The uses of this method for large vessels are, however, limited, and it is to be doubted if the evenness of tension is as complete as in thrown ware. The torsion of the clay obtained upon the wheel is most effective, and this spiral formation of the mass gives greater elasticity to the ware in expansion with rapid heating. In order to illustrate the direction assumed by the particles of clay in the formation by both methods, I have prepared examples in stratified coloured clays, from which it is evident that the movement of the clay in the two methods is altogether different, torsion or welding of the interior of the mass in the case of machine moulding being very limited.

4. Slip Moulding.—For small articles in which extreme lightness is required, "slip moulding" is resorted to. By this plan the plaster mould is entirely closed except one small hole, through which clay about the consistency of cream is poured until the mould is filled. The porosity of the plaster causes some of the moisture of the liquid clay, "or slip," to be absorbed, and a small quantity adheres to the walls of the mould. The rest is poured out. In a short time the thin vessel resulting is stiff enough to be removed for drying. This method is chiefly useful for articles of simple form, any details in the mould being rapidly worn away.

5. Expression.—This method is so well known in connexion with drain pipes that it hardly needs description.

The clay is usually filled into a chamber which is afterwards closed by a piston (see Fig. 2). Pressure on this is exerted by hydraulic, steam, or screw power, and forces the clay either laterally or vertically through an orifice of any required section. A great variety of sectional form is thus possible, but only articles with parallel sides can obviously be produced by this method.

With the introduction of improved machinery and experience it has been possible to turn out pipes of large diameter, and at some of Messrs. Doulton's works pipes of 3 ft. diameter, suitable for condensing towers, have for some years been successfully manufactured.

Fig. 2.

An interesting application of this process may be here noticed in the form of *spiral expression*. It furnishes a method of obtaining a very large condensing surface, and can be applied in various ways.

So far, manufacture by expression seems simple enough, and provided the section is one which allows an equal thickness of clay in all parts, almost any required form can be made.

In the case of bends and curves, however, the matter is not so easy. To produce a bend, the cylinder is filled with more clay on one side than the other. The flow of the clay through the die is consequently greater on that side. The workman, taking hold of the end of the pipe as it exudes, gently supports it in its curved direction (Fig. 3), but

Fig. 3.

without force. In proportion to the unequal filling of the cylinder, the angle of the bend will be more or less. It is, however, difficult to regulate exactly the flow of the clay, and there is always a tendency in the material to deviate from its original form in drying and burning. Correct angles cannot be maintained by this plan, and if accuracy is required, resort must be had to moulding.

The difficulty of making pipes of the form of Fig. 4 is, therefore, greater than that of Fig. 5 when accurate

Fig. 4.

Fig. 5.

dimension of span is wanted. Thus, in the case of long-armed connectors, though the flow of gas in 4 is easier, the uncertainty of dimension in 5 is less.

I wish also here to refer in passing to the admirable system of forming channels or half-pipes, by the "opercular" method introduced many years ago by Sir Henry Doulton. The pipe, as it leaves the die, is partially severed on each side through its whole length. Sufficient mass is, however,

left uncut to allow the pipes to be fired without separation. A sharp tap after leaving the kiln splits the pipe into two semi-circular channels.

6. *Plastic Die Pressing (as in Draining Tiles).*—By this method the rough slab of plastic clay is placed in a metal die or box of any given form, and a plunger exactly fitting the same is caused to descend by a screw. The clay, unable to escape, is pressed tightly into the box, thus taking its exact form. The plunger is now lifted, and the bottom of the box, being loose, is raised by a lever, so that the formed article supported on it can be carefully removed. (See Fig. 6.)

Fig. 6.

7. *Dust Pressing.*—An interesting modification of the above is obtained by filling the box with clay dust slightly dampened, instead of the plastic clay. With heavy pressure the particles of dust will adhere, and at one blow of the plunger a solid tile may be obtained. The shrinkage and warping are much less by this process, and the accuracy of form, therefore, greater; but the body is far more porous than if plastic.

8. *Grinding.*—The mechanical engineer who is able to turn his metal to any given size with the accuracy of 100th part of an inch knows none of the disappointment of the potter. Fitting is the "bugbear" of a pottery. After an article is formed it will shrink nearly three-quarters of an inch in every foot in drying and nearly as much more in the firing. But varying circumstances in the drying and firing will make a varying shrinkage, and an element of uncertainty is thus introduced, which it is impossible entirely to control, especially with large vessels fired in huge kilns at a very high temperature.

To obviate this, recourse is sometimes had to grinding, as in taps and pumps. This is done after the article is completed by means of emery and a revolving bed or lathe. The extreme hardness of the ware, however, makes the plan difficult and costly.

It need hardly be pointed out that all these methods have their own advantages, and it is necessary to choose the method according to the form.

We have next to devote our attention to some of the—

E. *Difficulties of Manufacture*, as related to the form itself. The great object to be attained is *uniformity of tension* in drying, in firing, and in use. Though many other matters tend to assist this, equality of thickness is perhaps the most important for this result.

1. IN ARRANGING THE FORM OF THE VESSEL the following points should be noted:—

(a.) *The shape should be such that if possible it has a suitable base to stand on in drying and firing.*

Thus the form shown at Figs. 7 or 8 should be adopted and not 9. In large vessels, say of 50 gals. and up, forms 10 and 11 would be almost impossible.

Fig. 7.

Fig. 8.

Fig. 9.

Fig. 10.

Fig. 11.

(b.) *The form should not tend to collapse.* Thus form Fig. 12 not 13 should be adopted.

Fig. 12.

Fig. 13.

(c.) *The position of fittings should not be made to depend on accuracy of form; thus, the connections of Fig. 14 may become as 15 through sinking in firing.*

Fig. 14.

Fig. 15.

(d.) *Nor upon freedom from torsion in ware as with a gauge glass socket.* (See Fig. 16.) In this case the twist of the clay through making on the wheel causes the position of the sockets to shift from the perpendicular in the firing.

(e.) *It must also be noted that forms thrown on wheel and cut are to be avoided; thus Fig. 17 would be sure to twist (see Fig. 18), also still-head dip-arm in one piece would be very uncertain, as in Fig. 19.*

Fig. 16.

Fig. 17.

Fig. 18.

Fig. 19.

(f.) Parts necessarily made by different methods have different shrinkages and cannot be struck without risk.

Thus, pipes stuck inside thrown vessels are to be avoided on account of both torsion and shrinkage, as in Fig. 20.

Fig. 20.

2. IN DRYING.—The following should be avoided:—

(a.) *Unequal thickness.*—The contraction takes place more rapidly in the thinner parts and cracking results.

Thus, a thin copper may be suggested for economy of fuel and easy expansion, and if this is of large size additional thickness of flange might be asked for as adding to strength, but it is necessary to avoid the unequal contraction caused by this arrangement, and substitute 22 for 21.

Fig. 21.

Fig. 22.

(also do not bolt through a flange but outside it).

(b.) *Unnecessary Width of Base.*—The large diameter of base should be avoided and reduced as much as possible, especially in large vessels, as the great weight prevents the mass from contracting at the bottom and cracks result in drying. Thus Fig. 23, not 24, should be adopted—

Fig. 23.

Fig. 24.

3. IN FIRING.—The following should be noticed:—

(a.) *Projecting Parts* requiring support entail great risk.

The whole kiln when at full fire is in a state of semi-fusion, and the sinking of projecting parts can only be

avoided by most careful adjustment of clay supports, the shrinkage of which must be precisely the same as that of the vessel, or cracking will ensue. (See Fig. 25.)

Fig. 25.

(b.) *In Pipes great length means great risk.*—The method of placing in the kiln may be either vertical or horizontal. In the former the play of fluctuating fire-draughts direct on the ware causes warping. In the horizontal setting, allowance for free contraction of length is very difficult.

It would of course be possible to point out many other examples of undesirable form, but the principles of construction are perhaps already sufficiently indicated.

F. *Connections.*—The efficient connections of chemical apparatus is a matter of great importance to the chemical engineer. The means being greatly varied, it may be of interest to note the most important of these.

1. *Butt and Collar.*—The chief difficulty is in packing this joint, and it is most suitable for a run or cast joint, a small hole being left in the collar for the purpose. It is, however, very rigid, and a modification suitable for many purposes at moderate temperatures can be arranged by using an india-rubber collar bound with wire.

Fig. 26.

Fig. 27.

2. *Butt Socket.*—A very compact joint where space is confined, but the manufacture of the ware is troublesome, being liable to warpage and chipping of the outer wall of the socket owing to the thinness of this part of the pipe on which it has to stand in drying and firing.

3a. *Butt Grooved.*—This is also open to the same objection of weakness in the socket butt. Besides this, in case of warping the grooves do not coincide and a bad joint results.

Fig. 28.

Fig. 29.

3b. *Butt Grooved Keyed.*—The groove may be counter-sunk, but this is even more difficult in manufacture and further weakens the butt. By leaving two small holes in the outer edge of the pipe a run joint of great strength and rigidity can be obtained.

4. *Spigot and Faucet* is undoubtedly the best joint for ordinary purposes and easily connected by unskilled workmen.

Fig. 30.

Fig. 31.

5. (Stanford's Patent) and 6. (Doulton's Patent) are most useful modifications of the above for purposes which do not require a temperature above 100° F. The spigot and faucet have cast on and in them a lining of tar or asphalt composition by means of accurately fitting dies which produce a true spherical joint. The pipes can therefore be fitted together perfectly tight without luting or cement, yet are able to be adjusted to slight curves of line and can be rapidly removed if necessary.

6. The faucet is cylindrical and the spigot spherical. The joint can thus be kept tight though the length of the run may spread slightly, which is not the case with No. 5.

Fig. 32.

Fig. 33.

7. *Screwed Socket*.—This can only be successfully applied to connexions of small diameter, say up to 1½ or 2 in. It should be noted that the allowance for warpage must be less than the depth of the thread, and this is not usually sufficient in larger sizes for so vitreous a material as stoneware. For this reason also coarse threads are desirable.

8. *Taper and Fillet* is only suitable for long pipes used vertically and of diameters under 9 in., as the joints cannot be made tight if the pipes are warped.

Fig. 34.

Fig. 35.

9a. *Butt Ground and Luted*.—This method is chiefly applied to jointing of stills and still-heads.

Fig. 36.

Fig. 37.

9. *Clay Lute*.—This is the usually accepted joint for receivers and stills, and for all arrangements where rapid disconnection is required nothing can excel it. It is capable of easy adjustment to irregularity of level, and if suitable luting is used there is little danger of this falling into the vessel.

9b. *Socket Clay Lutes* are preferred by some, but on the whole there is more difficulty in keeping out the luting by this plan.

10. *Water Lute* sockets need little explanation. The greater the depth, however, the more risk of warped and ill-fitting connexions.

Fig. 38.

Fig. 39.

11. *Fill and Groove* is a good serviceable joint and very tight under pressure with india-rubber rings in the hollow. The flanges need to be very strong and the bolts should pass through the clips outside and not through the flanges.

12. *Ground Flange and Groove*.—In this case the strain on the flange is greatly reduced and india-rubber flange can be placed between the two ground surfaces which thus get a true bearing all over when screwed up. The india-rubber expands sufficiently into the groove to prevent it from blowing out under pressure.

Fig. 40.

Fig. 41.

13. *Butt Ground Flanged*.—This patent joint (made by Messrs. Doulton) is very useful where rigidity is not an objection. The butt ends are ground true and the pipes held together with wooden wedges and iron clamps.

14—15. *Packed Gland Joint* (as in pumps). This needs no explanation, but in all cases the bolts should be carried outside the ware.

The greatest care is needed in screwing up bolts with so rigid a material as stoneware, and no undue strain should be thrown suddenly on any one point.

Fig. 42.

Fig. 43.

It should be noted that extreme accuracy in jointing, such as is sometimes attempted with ground surfaces and bolts, is liable to defeat its own purpose by its undue rigidity.

Each joint being butt ground, no play in position or length is possible, and the whole apparatus, when screwed up, becomes rigid and incapable of adjustment to levels or even to the slight warping of pipes which is inevitable with all stoneware. A more serious objection is that no opportunity for expansion and contraction in length is possible, and it is therefore important in all such arrangements that *expansion joints* as shown at Fig. 44 should be introduced.

Fig. 44.

G. Methods of Heating.—The application of heat to stoneware vessels requires considerable care, and successful results in its use depends much on suitable arrangement.

The power of conduction in stoneware is very limited. It is needful, therefore, to distribute any sudden change of temperature over the whole surface of the vessel as much as possible. If this is not done the heat directed on one portion causes this to expand before the transmission of the heat to other parts has taken place and fracture is liable to ensue. For this reason any method which allows rapid circulation of the heat to all parts is to be preferred. Therefore a steam jacket or a water-bath is much better than a sand-bath.

It is true that the latter allows of a higher temperature being transmitted to the vessel, but the heating is less uniform and cannot be so readily diffused through the sand.

In working with jacketed vessels much care is needed to protect the stoneware from the direct action of the inflowing heat, by a "baffling" piece.

In cases where the jointing of the vessel to the jacket is by means of a flange it is necessary to remember that the additional thickness at this part prevents the equal expansion. Also that the part, if any, above the flange being generally exposed, and therefore colder, will not expand to the same extent in heating.

For these reasons the heat should be applied somewhat lower down in the jacket so that the undue strain may not occur in the first application.

Some experiments were made several years ago, in which I assisted, under Coffey's patent, when stoneware vessels were heated to high temperatures by means of heavy paraffin oils circulating in closed jackets. The results were considered satisfactory and a temperature of 520° F. was obtained in the vessels without fracture. The oil itself was worked up to 800° F. on leaving the furnace. Considerable care, however, is required to obtain oil free from resins which clog the pipes, and it is needless to say that very steady circulation has to be maintained to prevent the oil being overheated.

Another method of heating is by steam coils inserted in the vessel, the heat being transmitted through the coil to the liquid. If the nature of the operation will allow it, and a suitable material can be obtained for the coil, this plan is very satisfactory.

A more risky plan is the introduction of steam into the vessel itself. The concussion resulting from this arrangement is very liable to cause fracture, and every means should be taken to lessen the vibration, if it is resorted to. The vessel may be enclosed in a wooden or cast-iron jacket and filled up with cement, concrete, loose sand, asphalt

composition, or sulphur and sand mixed in suitable proportions according to the temperature required.

The temperature which it is possible to apply to stoneware is only limited by the fusibility of the material itself. Any temperature up to this point can be successfully used, providing it can be applied equally to all portions of the vessel at once; and also that the application is sufficiently gradual to allow of the penetration of the heat through the mass as well as its action over the surface. It is, however, usual at the ordinary thicknesses and by the methods now in use, to recommend the employment of stoneware up to about 400° F. Beyond this point other bodies are to be preferred and special mixtures need to be introduced partaking more of the nature of fireclay in their composition.

The capability, however, of rapid expansion and contraction without cracking is a quality not so easily obtained. It can only be secured:—

1. By making the material very thin, so that there is not a great mass for the heat to penetrate.
2. By making the body coarser, so that the heat may penetrate more rapidly.
3. By the most careful annealing of the vessel during firing, so that the particles of the mass are not in any undue state of tension.
4. By using such materials as in themselves are liable to comparatively small contraction or expansion.

It is therefore only by the consideration of each chemical process according to its requirement that the best adjustment of the above methods can be arrived at. The coarser the body, the more porous the vessel. The thinner the vessel the weaker for use and the more risk of warping and breakage in manufacture. The less the contraction of the material, the more friable the body of the vessel itself.

H. Pressure and Resistance.—I regret that the length of the present paper does not permit of my placing before you to-night any important facts in relation to this part of the subject. I hope, however, to have this opportunity on some future occasion. Meanwhile I wish to draw your attention to the following table, which gives the result of some few materials, although not directly relating to chemical stoneware.

It is, however, clear that the variation in the bodies used for chemical operations is so considerable that no definite information can be tabulated as to the strength, this being also partly dependent on the thickness and form of the vessels. (See Tables D., E., F.)

It is important to note that the thickness possible is limited, and cannot be increased proportionately with the size of the vessel. The pressure allowable, therefore, rapidly diminishes with increasing circumference. For this reason, if practicable, the strength of large vessels should be supplemented by the additional support of bands or jackets, and when these can be so arranged as to prevent the undue expansion of the vessel, and also equalise the strain, in this respect a very important result has been attained.

The comparison of the figures in Table F., Nos. 1 and 2, shows that even a partial support greatly increases the stability of the vessel.

I. Special Apparatus.—It has not been the intention of the present paper to enter on so wide a subject as the special

application of various constructions or to describe the great variety of forms in which this material is manufactured. I may perhaps, however, be pardoned for bringing to your notice one such arrangement in evidence of the progress made, and which I think you will allow is a creditable instance of technical difficulties successfully overcome. I refer to the stoneware acid force pump. Some years ago I conceived the idea of producing pumps in stoneware, and after making such modifications as experience showed to be necessary, we have been able to turn out for some time past acid pumps up to 6-in. bore such as you see before you. The plungers are accurately ground, and the packing is of asbestos or india-rubber, as may be most suitable. The valves are of stoneware, and the valve boxes are inter-

changeable, being also removable without detaching the pump.

I have also ventured to call your attention to the stoneware slabs for sectional acid tanks. By means of powerful and accurate machinery the edges of these slabs are ground to a true face, and can be used for lining tanks of other material or bolted together with care in a similar way to cast iron. For some purposes this system is very useful, and is the only method under which stoneware can be applied to the manufacture of vessels too large for producing in one piece. Much of the success of this plan, however, depends on the use of suitable cement and considerable care in the arrangements for bolting up the structure.

DISCUSSION.

The CHAIRMAN having invited discussion on the paper:

MR. DAVID HOWARD thanked the author for his clear exposition of the conditions under which stoneware chemical apparatus was produced—which conditions ought to be constantly borne in mind by the chemists who used the apparatus, in order to successfully carry out operations on a large scale. Few of them were such adepts in the subject that they would not gather much that was useful from the paper. One point which came out very clearly was that they must not insist strongly on perfection of form in such apparatus, for when secured it was generally at the expense of the quality of the ware. The great advances recently made by potters in adapting the character of their wares to various purposes was a striking illustration of the modern development of this most ancient of manufactures. But to attain that end it was essential that the potter should be fully informed as to the uses to which his wares were to be applied. One result of the reading of the paper would be to make chemists far more careful how they applied stoneware apparatus to unexpected purposes.

MR. W. CROWDER inquired whether the author had any experience of the use of the acid pump exhibited, in dealing with sulphuric acid. Seeing that there were several valves in the apparatus, he would like to know how long they might be expected to last, and also whether the valve seats were likely to wear out. It seemed to him that even if the worn-out valves could be replaced by new ones the leakage of the seats was likely to cause trouble. Again, in the case of the plunger of the pump, it hardly seemed possible that any provision could be made for keeping it tight after it had begun to wear. He understood that at present the pump was principally used for hydrochloric acid; but if Mr. Rix could reassure him on the points he had raised he thought that the pump might be used with great advantage for dealing with sulphuric acid, and for many other similar purposes.

MR. WATSON SMITH agreed with Mr. Crowder's remarks. In 1873, a firm with which he was then connected purchased a stoneware hydrochloric acid pump, and during the process of erection, part of a flange, including portion of a bolt-hole, was broken off it. On inquiring whether the pump could be repaired, his firm was informed that no cement then existed which would repair the apparatus satisfactorily, and that consequently it would be necessary to buy a new pump. That unpleasant experience led him to inquire whether there was at the present time any effective material for cementing together the parts of stoneware apparatus for chemical uses. If not, was it possible to obtain new portions of such a composite piece of apparatus as an acid

pump, for example, to replace those portions which might be slightly broken, so as to avoid the expense of repurchasing a whole pump or other apparatus?

Mr. G. D. MacINDOE wished to know what amount of pressure the acid pump might be relied upon to stand. Pressures of 40 to 50 lb. were common in dealing with acids. Would the pump shown stand a pressure of 80 lb.?

Mr. W. P. Rix, in reply, said that great progress had been made since 1873 in the manufacture of such apparatus as the acid pump shown, its whole arrangement having been entirely remodelled to meet the difficulties which experience had shown to arise. The pump now stood on its own base, and as the body was not now cylindrical in form, like the pipes exhibited, it could easily be bolted to any suitable foundation. The valve boxes were now made interchangeable, and formed no portion of the pump itself. It was also possible to grind the valves with emery, and fit them on the spot. With regard to the leakage or breakage of the valve seats, he could assure Mr. Crowder that they were now made sufficiently strong to bear any strain that was likely to be put upon them. With respect to the breaking of flanges, he had already pointed out that extreme care was necessary in bolting stoneware. It being absolutely rigid, more rigid even than cast iron, unless the bolts were carefully screwed up all round, so as to avoid any undue pressure on one part, fractures would occur. Such breakages were generally due to the fact that the workmen were accustomed to deal only with metal apparatus, and forgot the extra care that was required in the case of stoneware. With regard to Mr. Crowder's question as to the arrangement of the plunger, he would point out that it was ground only into the stuffing gland, and not into the barrel, a small space being allowed between. The strain thus fell only on the packing, which could be renewed. If, however, the stuffing gland became worn, all that was necessary was to send it to be ground to a new plunger. The question of the pressure to be put on such a pump was, of course, of great importance. In the case of the 6-in. pump, the pressure on the valve box cover was considerable, and there was need of great caution in using high pressures; but there was no such difficulty in pumps up to 4 inches. In pumping such a dense liquid as sulphuric acid it would not be possible to attain so high a pressure as in dealing with hydrochloric acid. They were accustomed to test their acid pumps up to 35 lb. to the square inch when required, but he would not like to undertake a pressure much above 20 lb. unless it were specified, in which case the valves and other parts would have to be made extra strong for the purpose. But for ordinary purposes, and with pressure up to 25 lb., there should be no difficulty in using these pumps. He trusted that the explanations he had given would be sufficient, and that an examination of the pump by the members would convince them that it was a useful and efficient apparatus.

One of the earliest patents for accelerating the process of tanning by mechanical methods is that of Francis G. Spilsbury of Walsall, Staffordshire, and is dated 1823. He used oblong frames of wood and stretched the hides on these, placing a frame between and thus forming a vessel, having stretched hides for its sides. Into this vessel the tanning liquor was run through a pipe from an elevated tank, pressure being regulated by the hydrostatic head. The hides became distended and the liquor oozed out forming drops like dew. By this process it is said that the hides could be tanned in six weeks, or in some cases in eight or nine days, instead of a year. The process was abandoned, owing to the trouble entailed in closing any holes or tears in the hides and the considerable waste caused by cutting the hides to fit the frames. Another early invention for hastening tanning was that of T. J. Knowles, who employed an air-tight vat. The hides were suspended in the liquor from hooks at regular intervals, and were provided with leaden weights to keep them uniformly stretched. The air was exhausted by a pump, and after an interval the liquor also was removed and the air admitted. This process was repeated until the tanning was accomplished.

One of the first applications of mechanical motion was that of W. Brown, of New York, who employed a reel or cylinder, composed of two heads and a number of longitudinal bars with pins on the outer surface on which the hides were fastened. He also threw them loose into the cylinders, which were slowly rotated by means of ratchet gear. In America, a rocking bar was used, the hides hanging from it and alternately dipped into the liquor and withdrawn from it. A modification of this consisted of a frame moving up and down, dipping the hides in the vat. These and other mechanical methods were used for the simple purpose of obtaining a continually fresh application of the tanning liquor to the surface of the leather, instead of the ordinary daily handling of the hides. These mechanical processes may be broadly divided into two classes: those in which the hides are allowed to hang or are stretched on frames, and those in which they are rolled or churned loose, in bulk. In the former class, the stirring of the liquid is practically as efficient as in the latter, but there is no tendency to remove the soluble or soft gelatin and albumen by kneading and churning, and the hides being always surrounded by the liquor, the tannage proceeds uniformly in every part.

So far, the mechanical processes are designed for an obvious purpose, but when we come to the application of electricity to tanning, we find that the inventors are groping in the dark, using a powerful operator, but with no rational principle or motive. The only *a priori* reasons for applying an electric current to a hide in a tan pit are, that some electrolytic action may liberate some tanning agent in a nascent state, and that dialysis is accelerated by the passage of a current, and that there is a relation between osmosis and electrolysis.

As early as 1849 a tanner named Crosse proposed to utilise "electricity or galvanism for tanning purposes." The electrodes consisted of sheets of zinc and lead, immersed in an ordinary tan-pit in which water and the hides were placed, bark or other tanning material being added from time to time, after the skins had been subjected to this action for some days. Ward, in Lancashire, some years later, passed a current of electricity through the tanning liquor in ordinary tan-pits. In 1861 Rebu made several experiments on electrical tannage, employing various metallic salts as well as ordinary liquors in his pits. In 1874 de Mertens, of St. Petersburg, turned his attention to the subject, and has for some years adopted in nearly 600 pits the following plan of electric tanning. A layer of carbon connected with the positive pole of a dynamo is placed at the bottom of each vat and it is then filled with the alternate layers of moist skin and tan, a plate of zinc forming the negative pole at the top of the vat.

In 1876 Lucier Gaulard, and Kresser proposed another process in which they used two parallel plates of carbon, and immersed the hides between them in tanning liquor, passing a continuous current of electricity through from plate to plate. Leather made by this process was exhibited in London in 1883. The process of Landin and Abou has been worked for more than two years in the tanyard of

TANNING BY THE AID OF ELECTRICITY.

BY DR. S. RIDEAL, F.R.C., F.C.S., AND A. P. TROTTER, B.A.,
A.M.I.C.E., A.I.E.E.

THE slow rate at which a hide is converted into leather in the ordinary process of tanning has induced many inventors to devise methods by which the chemical change might be accelerated without deterioration of the quality of the leather produced, but the want of any definite knowledge as to the precise nature of the interaction which takes place between the gelatin of the raw hide and the various tannins employed in this industry has been a serious obstacle in the development of these methods, and many of the proposals after having been tried on a small scale have been abandoned in favour of the old and slow process. It is necessary to refer to some of these proposals in order to understand the position of the industry a few years ago, when the first important steps towards the employment of electrical energy for hastening the tanning process took place.

Messrs. Nielson of Norrköping, in Sweden. Here, the hides are attached to wooden frames and are placed in a pit. Large copper electrodes are provided, and an alternating current is passed.

A simple combination of motion and electrical treatment was patented in France by Worms and Balé in 1887 (this Journal, 1888, 41, 587), and consists of a large drum, some 11 ft. in diameter, mounted on a horizontal shaft and filled one-third full of tanning liquor, together with some turpentine, and in this half a ton of hides are placed loose in bulk. The drum is set in motion by steam power, and a current of about 10 amperes is passed through the contents by means of copper electrodes placed on the interior surface of the ends of the drum. Nicholson and Palmer (Eng. Pat. 9776, 1889) have also described a similar process, in which the hides are suspended on the positive electrode within the rotating drum, and the current of electricity is caused to flow mainly through the hides.

Another distinct process is to be found in the Groth system of tanning (this Journal, 1888) a description of some of our experiments on which forms the subject of the present communication. In Groth's apparatus there is a combination of motion and electrical treatment, but the motion is of such a nature that the hides being left stretched and suspended in the liquor, are not churned about or rubbed one on the other as in Worms and Balé's process.

The two practical forms in which Groth's invention has been worked at the Grange Works, Bermondsey, are first, a round vat containing a revolving frame carrying the hides, and secondly, a rectangular tank in which a similar frame is carried to and fro, running on wheels, and moved by a crank. One of the circular vats placed at our disposal was 7 ft. 3 in. in diameter and 6 ft. 4 in. deep. The cubic contents were thus about 315 cub. ft. or nearly 2,000 gallons. The sectional area in a vertical plane is about 43½ sq. ft., the superficial area in plan is 12 sq. ft. A strong central shaft turns in bearings and is driven by bevel gear, the arrangement being precisely like a brewer's mash tun. Wooden arms are attached to the shaft and carry cross pieces. These are provided with a number of brass hooks, by means of which the hides are hung vertically, about an inch apart, all the metal work in contact with the liquor being brass or copper.

Electrodes are placed against the sides of the vat. These consist of strips of copper arranged gridiron fashion. Four strips 4 ft. 3 in. long by 2 in. wide are placed 8 in. apart, and are connected at the top and at the bottom by strips of similar width. The whole surface exposed is therefore about 4 sq. ft. Experiments were also carried out in a rectangular vat in which the hides were moved backwards and forwards longitudinally.

The tanning liquors were made of the usual materials, and during the tanning were strengthened from time to time in the usual way, and the hides were prepared for tanning by liming, unhairing, fleshing, and colouring as practised by most tanners.

The current was varied in different experiments according to the nature of the hides and strength of liquor. This is important in order to obtain satisfactory results. Previously to our investigation a series of experiments, in which the current varied from 1 to 30 amperes, was employed; best results were obtained with the weak currents, and the considerable loss due to electrolytic action when a greater current was employed, was thereby avoided. With a current from 1½ to 4 amperes, the density is from 0.375 to 1 ampere per sq. ft. of electrode, and from 0.0345 ampere per sq. ft. of transverse sectional area of the contents of the vat to 0.092 ampere per sq. ft.

For currents from 1.3 up to 2.3 amperes, the total resistance of the liquor at 9° C., sp. gr. 1.01, expressed, for convenience, in ohms, was 8.7. On another occasion, at 7° C., sp. gr. 1.019, the resistance was 7.7 ohms, with 2.3 amperes. In each case the resistance was measured by observing the current and the volts between the electrodes. The quotient gives the sum of the ohmic resistance and of the polarisation. Exploration of the vat by means of a movable electrode showed that the flow of current was very uniform.

In our earlier experiments the current and voltage were observed, the vat being full of tanning liquor up to a certain mark. The hides were then put in, displacing a certain quantity of liquor. This was removed until it stood at the same mark as before, and the resistance was again determined. The results obtained in this way, however, did not give us any very definite information as to the variation in the resistance of the hides during their conversion into leather, but were sufficient to show that the hides when just immersed did not offer any material additional resistance to the electric current. Arrhenius (B. A. Electrolysis Report, 1887, 315) has previously pointed out that the resistance of solidified gelatin is not different from that of gelatin solution.

A more careful and accurate series of observations were subsequently made on the electrolytic resistance of the tanning solution, from which the following curves were obtained.

The temperature coefficient was, as might be expected, negative. The resistance decreased 0.9 ohm for a rise of 1° C. or 1.32 per cent. at 16° C., falling from 75 ohms per cubic inch at 8.6° C. to 59 ohms per cubic inch at 26° C. The liquor was a strong solution containing 4.25 per cent. of tannin, obtained from mimosa bark and gambier, such as was employed during the later stages of the tanning. The same sample was tested for the purpose of ascertaining the true ohmic resistance and the fall of volts due to polarisation with different current densities on the electrodes. The resistance of the given sample of the liquor at 8.5° C. was 82 ohms per cubic inch—11 *d* where *d* is the density in amperes per square foot of electrode. This is shown by the straight falling line in Fig. 1—

$$v = 82 - 11 d$$

The voltage lost at the surface of the electrode is not so simple a quantity. It tends to a minimum of 1.4 volts for a minimum current, and the two following empirical formulae closely approximate to the observed curve—

$$\text{Volts} = 1.4 + 45 d^{1.2}$$

$$\text{or} = 1.4 + 0.194 d + 8 d^2$$

where *d* is the density of current in amperes per square foot. This is shown by the rising curve on Fig. 1.

Fig. 1.

POLARISATION EFFECT.

A third series of tests were made to determine the change of resistance produced by diluting the liquor with water.

The curve of the results of the observations, shown in Fig. 2 by the dotted curve, which evidently bears a strong resemblance to a rectangular hyperbola, and on analysing it by plotting the relation of the product of the resistance into the strength, with the strength (taking the normal strong liquor of 4.25 per cent. of tannin as 100) the result

is a straight line, shown on the diagram, the slope of which is 63, and it cuts the axis of the abscissæ at 1200. The curve is, therefore, a rectangular hyperbola, that is to say, the resistance is inversely proportional to the strength of the liquor plus the resistance to which the curve is asymptotic, that is, the resistance of the saturated solution per cubic inch would be 63 ohms per cubic inch. The formula is therefore $r = \frac{120}{s} + 63$ where s is the strength of the liquor per cent., 100 being the normal solution referred to.

Fig. 2.

VARIATION OF RESISTANCE WITH STRENGTH OF LIQUIDS.

With the view of ascertaining whether the mechanical stirring of the liquor had any oxidising or other effect upon the liquor, a vat was filled, and the frame was kept rotating as in ordinary work, but without any hides, for 24 hours. Analyses of the liquor before and after this treatment gave identical results as far as the practical point of the percentage of tannin is concerned, thus showing that the stirring has no effect other than that of continually bringing fresh liquor to act on the surface of the hides. A similar experiment was made to determine the effect of passing an electric current of ordinary working strength for 9 hours through the vat simultaneously with the motion of the frame. At the end of the experiment the liquor contained the same percentage of tannin. This result was to be expected, as the electrical power is remarkably small and the current density in the liquor is far below that of any ordinary electrolytic operation. Taking the mean volts and amperes of the second test already mentioned, and deducting 1.6 volts for polarisation, we have 36.8 watts expended in the liquor. It is obvious that this very small power, about $\frac{1}{27}$ of a horse power, can have but little effect on 2,000 gallons of liquor. The electrolytic effect is negligible when such weak currents are employed, since a current of 2 amperes will only liberate from water .075 gram. of hydrogen and .6 gram. of oxygen per hour, or during the whole process considerably less than 10 grms. of hydrogen would be evolved.

In our earlier chemical experiments with this process, our efforts were directed towards establishing the rate at which the tannin is taken up by the hides with and without the use of motion and an electric current. It was also of interest to determine whether the rate of tannage in the circular vats, in which the hides were suspended on a rotating frame, was similar to that obtained when a square vat was employed, and the hides suspended on a frame to which a reciprocating motion was imparted as already described.

In these first experiments the rate of tannage was determined by noting the loss of tannin from the liquor after given intervals of time, and from the data so obtained calculating the average rate of loss per hour from the liquor.

The following table summarises the results obtained in three complete tannages in which the process was discontinued at night, so that the electrical current and motion was only applied to the experimental vat for from six to eight hours per diem:—

TABLE I.

Experiment.	Loss of Tannin per Hour per 10,000 Parts of Liquor.	
	Day.— With Motion and Electricity.	Night.— Without Motion and Electricity.
Circular vat 1, 1,600 gallons...	*62	*344
Circular vat 2, 2,400 gallons...	*612	*349
Reciprocating vat.....	*333	*338

The experiment in the circular vat 1 extended over a period of 26 days, during which time the machine was in motion for 167 hours, and a current of electricity applied for 98 hours to the 20 butts tanned in this experiment.

The second experiment in vat 2 lasted for 33 days, during 209 hours of which the hides, 30 in number, were in motion and a current of electricity passed for 115 hours.

In the reciprocating vat 40 bellies and 20 shoulders were in the liquor for 27 days, the machine was in motion for 181 hours, and a current of electricity simultaneously applied for 82 hours. In each experiment the hides were completely tanned when they were taken out of the vat, and when finished were reported to be leather of excellent quality.

Daily temperature readings of the liquor were taken, but on no occasion was the temperature markedly different from that of the surrounding air, 15 °C. being the highest reading recorded, and on some days the liquor being as low as 5 °C.

The following table gives the actual experimental numbers obtained in the second of the above tannages, from which the average numbers given in Table I. for this experiment were obtained.

TABLE II.
CIRCULAR VAT 2.

Strength of Liquor in parts per 10,000.		No. of Hours.	Total Decrease per 10,000.		Decrease per Hour per 10,000.
Machine Started.	Machine Stopped.				
A. With Electricity and Motion. Day.					
92.8	89.4	5	3.4	*68	
93.8	90.0	7	3.8	*54	
84.6	81.2	5.5	3.4	*618	
139.2	131.15	8	5.05	*63	
127.8	123.05	8	4.75	*593	
Average *612 parts per hour per 10,000.					
B. Night, at Rest.					
89.4	84.4	14	5.	*357	
90.4	93.8	15	5.6	*373

105.6	100.2	14	4.4	*38	
135.8	129.6	14	4.2	*3	
282.2	268.3	45	13.98	*304	
Average *349 parts per hour per 10,000.					

The concordant nature of the above figures, as well as similar ones obtained in the other two experiments mentioned in Table I. at first led us to imagine that the hastening due to the combined action of motion and the electric current

was expressed by these numbers. Further experiments to be referred to later, however, proved to us that the rate of absorption at night, after the action of the electric current had been continued for some hours during the day, was much greater than that observed when the hides had not previously been subjected to this influence; in other words, the increased rate of absorption continued after the machine was stopped and the current was switched off. This effect may in all probability be attributed to the fact that as the hides pass through the liquor, the pores of the skins become distended and thus facilitate the passage of the liquor through the hides, which remain in this distended state for some time after they are brought to rest and the electric current cut off. When the machine is at work the hastening is further increased by the motion of the hides in the liquor augmenting the frequency of contact of the tannin molecules with uncombined gelatin, and when the current is passing a further hastening is no doubt due to the increased motion of the tannin molecules through the liquor which such current imparts to them and its disposition on the suspended hide. An endeavour was also made to trace the change taking place in the hides during the absorption of the tannin, and from the series of numbers obtained it was noticed that the percentage of water present in the well-drained hide gradually diminished as the tanning became more complete; the fleshed hide containing approximately 77 per cent. of water and the leather as taken out from the vat from 45–55 per cent. according to the part of the skin examined. A gradual increase in the specific gravity of the dried skin was noticed, 1.062 being the lowest and 1.119 the highest specific gravity obtained. Samples of the leather obtained in these three experiments were subsequently tested by the Kjeldahl process and nitrogen contents ranging from 7.35 to 6.99 were obtained. Very little is apparently known as to the nitrogen contents of finished leathers, and although Bottinger (Ann. 244, 229) has shown that the compound of gelatin with oak bark tannin contains 9.4 per cent. nitrogen, and oak-bark tanned leather from 9.03–9.24 per cent., he has pointed out that both of these bodies are decomposed on heating with water, yielding a soluble compound of greater nitrogen content and an insoluble body containing only 7.79 per cent. nitrogen in the former case and 6.17 per cent. in the latter.

It is obvious that if the nitrogen content of a leather can be regarded as an indication of the completeness of the change, that simultaneous determinations of the actual quantity of tannin taken out of solution by an unknown weight of hide substance and their average nitrogen content, would give data which would be of value to the tanner and enable him to predict the weight of his finished leather, and at the same time tell him the cost of the tanning material consumed in the work. Considerable difficulty was at first experienced in obtaining samples of the hide from time to time during the tanning that would represent the average composition of the leather. By taking the precaution, however, of taking the samples from a thick hide along the median line of the back from day to day, the error due to the varying thickness of different hides was reduced to a minimum, and the samples taken were then divided into two portions, one of which was dried at 100°, rasped, and the filings analysed, whilst a second portion was frozen, reduced to fine shavings by means of a microtome, dried, and analysed, and thus gave a check on the former value. As these are probably the first experiments in which a thick sole leather has been produced in a time sufficiently short as to render it possible to trace the gradual diminution in the percentage of nitrogen in the hide with its absorption of tannin from the ooze, we give a table showing the results obtained in a recent experiment.

Thirty specially selected green hides were marked and weighed, limed in the usual way for six days, unhaird and fleshed, but not scudded, washed and coloured in a weak liquor for two days. Their total weight was 2,322 lb., of which the horns, &c. weighed 104 lb., giving a net weight of 2,218 lb. used. The wet fleshed hides when introduced into the vat weighed 1,673 lb., and after the tanning was completed on the 22nd day, the wet leather taken out weighed 2,040 lb. The leather has since been finished

and the weight in the dry and finished state was 986 lb. The hair sold weighed 714 lb. and the flesh 569 lb. The following table gives the composition of the leather at different stages of the tanning and the amount of tannin disappearing from the solution.

TABLE IV.

Date.	N. Per Cent.	Weight of Tannin absorbed in lbs.
Fleshed hides:		
February 26th	16.75	..
February 28th	14.43	103.3
March 2nd	12.14	258.4
March 4th	10.56	490.3
March 9th	8.95	656.4
March 12th	760.0
March 20th	7.50	775.2

It will be noticed that the absorption after 12th March was very slow, and that the total gain in weight estimated from the tannin absorbed during the following eight days only amounted to 15 lb., or about $\frac{1}{2}$ lb. per hide. This slight increase in the weight, unless it markedly affects the quality of the leather, cannot possibly compensate for the extra time and power spent after the 14th day. In this experiment the 775 lb. of tannin consumed were obtained from mimosa bark and gambier, and for estimating the cost we may assume that 625 lb. were obtained from the bark, and 150 lb. from the latter. A 35 per cent. bark at 16l. 10s. per ton would furnish 625 lb. of tannin for 12l. 9s., and a 59 per cent. gambier at 34l. per ton would furnish 150 lb. for 4.55l., making a total cost for the tannin materials consumed in tanning the 30 hides, 17.45l. Other materials would, of course, work out to a different cost, and if valonia or oak bark had been employed the cost of tanning would be considerably less.

It will be seen from the above figures that a very large amount of tannin was absorbed during the experiment which was not present in the finished leather obtained. We believe that this result is due to the large portion of the tannin consumed being deposited on the surface of the semi-permeable membrane, and subsequently being removed when the leather is washed and during the finishing process. The difference between the amount found in the finished leather and the amount lost by the liquor during the tanning can, of course, be utilised for further work. Ostwald (Zeits. Phys. Chem. 6, 71) and Tammann (Zeits. Phys. Chem. 6, 237) have recently drawn attention to the deposit of copper in this way from a copper solution on the surface of a semi-permeable membrane of copper ferrocyanide, and it would seem probable that after the gelatin tannin compound is formed the deposition of tannin continues, but on the surface only of the leather. If the experiment had been stopped earlier, the quantity of tannin absorbed would have been less, and the amount removed from the surface in the finishing process also less.

Bottinger's experiments already alluded to point to a direct condensation of the gelatin and tannin taking place in the conversion of hide into leather, but so far as we are aware, there have hitherto been no direct experiments that this absorption took place gradually, and that there was a definite relation between the tannin lost by the liquid and the nitrogen content of the hide.

From analyses of the fleshed hide and finished leather the decrease in the nitrogen value and increase in the oxygen per cent. has been repeatedly pointed out, but by those who held that no definite compound was produced, this change was attributed to the direct oxidation of the hide substance and loss of nitrogen as ammonia. The above experiments go far to establish that when tannin is employed the conversion of the hide into leather is due to a combination or condensation of the gelatin and tannin.

We have not been able to ascertain what is the maximum amount of tannin which a given weight of hide will chemically absorb, but many of the samples of leather prepared by the ordinary process contain less tannin than the above. It is obvious that, provided the quality of the leather is equally good, the tanner, instead of aiming at the maximum yield of weight, should strive at the minimum yield, when tannin is worth more per pound than fleshed hide and conversely, when the economic conditions are reversed. The limits for a good leather appear to be approximately

40—60 per cent. hide substance, in union with 60—40 per cent. "tannin."

At present it is customary to judge of the quality of the leather from its appearance and colour; a hide is, however, frequently struck through when it has only absorbed a comparatively small quantity of tannin, and the colour of the finished leather varies considerably with the kind of tanning materials employed.

In Fig. 3 the daily absorption of tannin from the liquor in the above experimental tannage by this process

Fig. 3.

DIAGRAM OF COMPLETE TANNAGE. GROTH'S SYSTEM.

is shown, in which it will be seen that the rate of absorption as already shown in Table IV, gradually diminishes as the hide becomes saturated with the tannin, and finally the rate becomes so small that the ordinary permanganate valuation of the liquor is useless for estimating the change.

In Fig. 4 the daily readings for a similar experiment are plotted out and show analogous results. The readings were, however, discontinued on the 11th day, although the

Fig. 4.

DIAGRAM OF COMPLETE TANNAGE.

Feb.

quantity of tannin absorbed by the hides used in this experiment was not sufficient to completely tan them. They were subsequently finished in another vat. From the foregoing results, we have sufficient data to establish the qualitative fact that the combined action of the motion and the electric current considerably hastened the rate of tannage. It was of interest, however, to ascertain, if possible, what was the average rate obtained when the hides were slowly rotated in the pit and when no current was passed through the liquor.

A comparative experiment was made to establish this point, the results of which are given in the accompanying diagram (Fig. 5). Two circular vats were employed, A. and B., containing 1,600 and 2,400 gallons of liquor respectively, made up to approximately the same strength. A batch of hides which had previously been limed, unhaired,

and fleshed under the same conditions, was divided into two portions, whose weights were in the ratio of the volumes of the liquor in the two vats, so that the loss of tannin per unit volume of the liquor is equal to the absorption of tannin per unit weight of hide in each vat. The liquor in both vats

Fig. 5.

DIAGRAM OF COMPARATIVE TANNAGES.

Feb.

was analysed at the commencement of the experiment (Feb. 14th, 4 p.m.), and the hides remained suspended in the liquor, without any motion or electric current being applied to them, for 44 hours. Samples of the two liquors were analysed and the rate of absorption in each vat deduced and found, as might be expected, to be practically identical. The subsequent treatment of the hides in the two vats was so arranged that the hides in vat 1 should be subject to the joint influence of motion and electric current, whilst those in vat 2 were under the influence of motion alone. The experiment was then repeated for a longer time, and after an interval of rest the conditions were reversed, the hides in vat 1 being subjected to motion alone and those in vat 2 to the joint action of motion and electric current.

The results are plotted together in Fig. 5, where the upper curves show the gradual loss of tannin from the liquor and the lower curves calculated from them to show the quantity absorbed by the hides (as during these experiments the liquors were not strengthened, the lower curves are the images of the upper). From the slope of the lines the relative rates can be obtained.

The following table summarises the above results:—

COMPARISON OF THE RATES OF TANNING.

Kind of Tanning.	Total Loss in Parts per 10,000.	Total Time in Hours.	Rate.
Ordinary tanning.....	12.8	88	145
Rest after motion and electric current	15.3	56	273
Rest after motion alone	15.7	56	280
Motion after electric current.....	8.6	24	36
Motion alone	18.8	38	49
Motion and electric current.....	53.6	38	142
Electric current after motion.....	50	24	247

Thus, while the initial rate in vat 1 was 163 parts per 10,000 per hour, and 101 parts per 10,000 per hour in vat 2, when a current of electricity and motion was applied to vat 1, and motion only to vat 2, the rate of loss in vat 1 rose to 243 parts per 10,000, and in vat 2 to 163 parts per 10,000. After an interval of rest, vat 1 showed a rate of 136 parts per 10,000, and vat 2 a rate of 152 parts per 10,000. It is to be noted, however, that the apparent falling off in the rate in vat 1 may be due not only to the gradual diminution as the tanning proceeds as already referred to, but to the electric current during the night of this experiment being smaller than during the day, or possibly interrupted for some time, as no electrician was controlling the experiment during the night in question. After an interval of rest the conditions were reversed, motion being alone used in vat 1, and motion and a current of electricity simultaneously in vat 2. The rates of loss were then found to be 136 parts per 10,000 per hour in vat 1 and 246 parts per 10,000 per hour in vat 2, thus confirming the previous figures and proving that the vats or proportions of liquor and hide employed in each were not affecting the comparison.

The average values thus obtained are in the proportion of—

Ordinary Tanning.	With Motion.	With Motion and Electricity.
133	153	248

or the rate of tanning under the combined influence of electricity and motion is four times faster than the rate when motion alone is employed, and 16 times faster than when neither are used.

We have not tried the effect of a current of electricity on the hides when at rest, although no doubt the tanning rate would be similar to that obtained when motion is employed, as the hides when at rest would not be uniformly influenced by the flow of the current through the vat, and the leather produced would therefore be unequally tanned. It ought also to be noted that these rates were obtained with the motion of the kind produced by the first kind of machine, and that no doubt other rates of tanning would be observed under the influence of other kinds of motion, and if no provisions were adopted for preventing the hides from being in contact with another, it is safe to assume that the rate would be considerably less, as the circulation of the liquor to every part of the hide would be prevented.

Theoretical Conclusions.—The original suggestion of Grothius in 1805, with its chain of molecules and bonds, its pairing and unpairing, formed a very fair working hypothesis, and has been gradually developed and elaborated until we are to-day confronted with a very serious complication of theories. Helmholtz has suggested that there is no tearing apart of the molecules, but that work must be done in separating an atom from its electrical charge, or in removing electricity from an atom of high specific attraction, and

giving it to another lower in the scale. Clausius considered that the molecules are always changing partners, that dissociation, in fact, is always present to some extent, and that the effect of the electro-motive force is to give direction to movements which are already going on. Arrhenius considers that dissociation is complete in very dilute solutions, but Traube maintains that such a view upsets our conceptions of chemical affinity, and makes the convenient assumptions as to the nascent state impossible, and flatly contradicts the theory of hydration. The idea of a nascent state has been to a large extent given up by chemists, but the ions undoubtedly are occasionally liberated in a form in which, although they do not readily combine with the other matters in solution, and are in a self-combined state, *e.g.*, ozone, they are in a very energetic condition. From *a priori* considerations, as we have observed, this nascent state or the resulting facilities for combination which arise from the cause whatever it is called, might be expected to facilitate the operation of tanning in the same way that it affects the operations of bleaching and treatment of sewage. But although the tannins are molecules of some complexity there are no grounds for supposing that dissociated molecules react with the gelatin of the hides, and we have no proof whatever that any such dissociation takes place in the tanning process. Turning to the question of dialysis and osmosis, we find dialysis to be a form of diffusion to which electrolysis has been compared by Wiedmann, who showed that the conductivity of an electrolyte may be considered as depending on the coefficient of diffusion of the components through each other. Dialysis is a selective diffusion, and is undoubtedly facilitated by the passage of an electric current, and it is easy to see that such an action must be extremely advantageous in the slow process of tanning, which is probably retarded enormously by the superficial coagulation which takes place almost at the moment of first contact of the green hide with the tanning liquor.

Theories of dialysis are at present incomplete, but Van 't Hoff's law of osmotic pressure and our knowledge of the migration of ions indicate the direction from which a satisfactory theory of the process may be looked for.

In the meantime the facts which have been established are of a very different order, so widely different indeed that hypotheses of osmosis and observations of the migration of ions are alike useless. Dr. Oliver Lodge's experiments with dilute H_2SO_4 give a velocity of about $\frac{1}{3600}$ cm. per sec. for H , and $\frac{1}{14400}$ cm. per sec. for SO_4 . With jelly and a slope of potential of 1 volt per cm. the velocity of Ba was $\frac{1}{36000}$ cm. per sec. and Cl and Br $\frac{1}{14400}$ cm. per sec. But with a slope of one-tenth of this, *i.e.*, about 1 volt per cm., the rate of progress of tanning is only about 0.25 cm. in 100 hours, or $\frac{1}{144000000}$ cm. per sec. or $\frac{1}{72}$ inches per annum.

It thus seems necessary to attribute part of the hastening effect to the direct action of the electric current upon the suspended hide.

Helmholtz and Ostwald have given considerable attention to the resistance of electrolytes, and it is pointed out that the degree of dissociation can be determined from the conductivity. Arrhenius concludes that the resistance is greater as the ions are more complex, and the tannin molecules are considerably more complex than any compounds that have yet formed the subject of careful experimental work. Not only have we a complex solution, but it is admitted that with weak currents secondary actions are likely to take place at the electrodes, and it is only with strong currents that the real ions are liberated. The fact that the rate of absorption of tannin distinctly diminishes with even four amperes shows that if any chemical action be involved it is probably some secondary action of considerable complexity, and that therefore there is no need for attempting to explain the process by an electrolytic breaking down of the tannin molecules.

Although it is difficult to advance any definite theory as to the effect of the passage of the electrical current upon the process of tanning, the increased rate is obviously due to the current hastening the chemical union between the bodies which are in a condition to combine. It is well known that chemical combinations which only take place

at elevated temperatures, can be induced to occur at ordinary temperatures, when an alternating current is passed through the mixture of the two bodies. Amines combine with aldehydes in this way, and Meritts (Eng. Pat. 16,947, 1889) has proposed to bring about etherification, and so effect the quick ageing of spirits by the help of an alternating current.

Dr. S. Ehrmann of Vienna has also recently shown that a moist skin absorbs salts very rapidly from their solution when an electric current passes, and Wagner has also proposed to administer cocaine by a similar process of cataphoric medication. In Ehrmann's experiments, in which a current of 10–20 milliamperes was passed from zinc electrodes through a solution of methylene blue, in two cups in which the hands of the observer are immersed, blue spots appeared on the back of the hand in the anode vessel and none on the other hand in the other vessel. The absorption was most marked where the hair and fatty glands are situated, and thus throws light on the fact that in tanning the process is most rapid on those parts of the skin and that the electric current has no doubt a distending effect upon the pores of the skin as indicated by our earlier experiments. Lithium chloride is similarly absorbed by endosmosis through the skin, and Edison has shown that gouty secretions in the fingers are speedily dissipated by the prolonged action of currents of 20 milliamperes. H. N. Lawrence and Dr. Harries have obtained similar results (Soc. Arts March 11, 1891). We believe that the hastening of the tanning process is of a similar character, and we draw attention to these experiments as analogous, if not confirmatory of the explanation of the process which we tentatively advance in this paper.

We have to thank Mr. Bawden, one of our assistants, and Mr. Fox Bourne for help in carrying out part of the experimental work of this paper.

DISCUSSION.

Mr. B. HOOPER, speaking as a practical tanner of 50 years' experience, could corroborate Dr. Rideal's statement with respect to the difference of time required for tanning by Groth's electric system and by the ordinary process. He had been daily at the tannery whilst five parcels of English hides had been working under Mr. Groth's system, and had regulated the application of the tanning materials used, which were all the usual vegetable substances, and no chemicals. He would challenge any tanner now working the same class of hides to produce leather such as they saw before them in less than six or eight months by the old process, whereas this leather was tanned in three weeks. All the other processes of quick tannage which had come under his notice had failed to produce leather equal in weight to that made by the old process; but tanning by the aid of electricity gave results as to weight of leather produced, colour, and quality fully equal to those produced by the ordinary method; and it was clearly demonstrated by Dr. Rideal that the saving in time was effected only by the aid of electricity.

Mr. W. F. ANDERSON was under the impression that the effect of electricity was to distend the skin, thus causing the fibre to be more open than usual. Perhaps that accounted for the advantages of the process. At the same time, he understood that electricity had a contractile effect on muscular tissue. He would be glad if Dr. Rideal could explain that point, for although it might not appear to have much to do with the subject, yet the fact remained that they had these two kinds of tissues on which it would seem that electricity had directly opposite effects.

Mr. J. SWINBURNE congratulated the authors on attacking so difficult a subject with so much success. He thought that the first thing to settle was whether tannin was an electrolyte or not. He would suggest that its penetration through some such neutral substance as agar jelly should be tried, with and without a current. The authors had argued that the electric current deposited tannin in the same way as it deposited copper in Ostwald's experiment. He thought there was no analogy; copper was the electro-

positive radicle of an electrolyte; tannin, if not a colloid, was either the whole electrolyte or the electro-negative radicle re-combined with hydrogen. Copper was frequently deposited on the porous pots in Daniell cells; but he was informed, this occurred only when the zincs touched the pots; in which case it would not be the same phenomenon as Ostwald's. The authors had been led to look for mysterious actions because they assumed that such a small current as that used could work such a quantity of tannin into the leather. They argued that one coulomb could only urge one electrical equivalent of tannin into the leather. The matter seemed to admit of very simple explanation. Suppose a dozen skins to be stretched across the vat at a given time, and an equivalent of electricity to pass, it would work not one, but 12 equivalents of tannin into the skins. But if mechanical agitation were applied, it would work tannin into the inter-stices of the skins, and if then electricity were applied it would cause the tannin to diffuse, or penetrate into the various mechanically impervious walls of the inter-stices of the hides. The result was, that when combined with mechanical agitation, a very small current was necessary to tan a large quantity of hide. There was no need to rely on obscure actions, such as deposition of films, or the suggested opening action of electricity on the pores of the hides.

Mr. CONRAD K. FALKENSTEIN said that during the last two years he had been working on the subject of electric tanning by a different process to that employed by the authors of the paper, and was therefore pleased to see the way in which they had worked out the problem. He had travelled over much of the same ground, especially with respect to the results given in Figure 3; and his results were almost identical with theirs, except with regard to the small absorption curves showing the variation in the strength of liquor during the progress of the tannage; the difference being due to the greater rapidity of the method employed in his experiments. A point in which he differed from the authors was in respect to the distribution of potential in the liquor of the drum employed in the Worms and Bale process. His own experiments showed that at any given point in the liquor the potential was proportional to the distance of that point from the electrode, and that there was a perfectly even distribution of the potential right across the drum. (Diagram given illustrating this point). With respect to the variation

FALKENSTEIN'S ABSORPTION CURVE.

of resistance with the current density, his experience agreed fairly well with that of the authors. In a four hours' test, the current remaining the same, the potential dropped to nearly half the amount, the drop reaching its maximum at about half time, and then remaining fairly constant to the end of the experiment. He considered that the effect of the current on the liquor was undoubtedly electrolytic, but the amount of electricity passing being very small, the effect was but slight. But it was certain that there was a definite relation between the amount of electricity passing through the liquor and the amount of tannin that became inert or was oxidised by the oxygen evolved at the positive pole. He very much admired the way in which the authors' experiments had been carried out, and the manner in which they had thrown light on the subject.

Mr. A. P. TROTTER, referring to Mr. Swinburne's statement that the particles of the leather being in series, the action which took place in one hide would follow naturally in another hide with the same current, pointed to the very small quantity of hydrogen evolved, and stated that only fifteen millionths of the liquor was decomposed, so that it was hardly possible to imagine that the action was electrolytic. An idea had been put forward that dialysis or osmosis might explain the effect produced; but the calculated speeds of the migration of ions were of such a different order that that theory would not hold. He was inclined rather to the old-fashioned idea of dialysis which had been ousted by the recent hypotheses of osmosis. But all that could be said was that dialysis was hastened by the passage of a current. He therefore thought that both the electrolytic and the osmotic theories must be put aside until we had more knowledge about the subject. The results shown on the lower diagram (Figure 5) indicated that it would be better to apply motion first and electricity afterwards, in order to get the most rapid tanning effects. The current density was so small that it could hardly account for the physiological effects referred to by Mr. Anderson.

Mr. J. SWINBURNE thought Mr. Trotter had misunderstood his argument. It depended not so much on the hides being in series, as the various particles of each hide being in series. At the slow rate at which radicles moved it was impossible for the tannin to be driven through a hide in the time, but if it were worked mechanically into contact with a cell, electricity would drive it in. Curve 5 showed that the current should not be turned on till the liquor had been thoroughly worked into the interstices of the skin. The electricity then took particles or fibres into the interior of the various cells and tanned the hide. If the electricity were turned on at first it tanned the outside and partially hardened the skin so that mechanical agitation then failed to work the liquor further in.

Dr. S. RIDEAL, in reply, said that with respect to the question put by Mr. Anderson, he could not see that the two effects were in any degree comparable, as the microscopical structure of skin showed that it was different to that of muscular tissue. In the paper they had referred to recent physiological experiments which seemed to bear on the phenomena under discussion. He was glad to hear from Mr. Swinburne that, speaking as an electrician, there was no difficulty in accounting for the deposition of the tannin upon the hides. He had not known that Mr. Falkenstein had been working in the same direction as they had; and it was all the more satisfactory therefore to find that their results were mutually corroborative.

ERRATUM.

Dr. Chas. A. Kohn, University College, Liverpool.

Notices of Papers and Communications for the Meetings to be sent to the Local Secretary.

The names in italics are those of members of Committee who retire at the end of the current Session.

The following have been elected to fill the vacancies and will take office in July next:—Chairman: H. Brunner; Vice-Chairman: A. Norman Tate; Committee: E. Carey, V. C. Duffield, and F. Hurter.

Meeting held on Wednesday, May 6th, 1891.

MR. A. NORMAN TATE IN THE CHAIR.

THE MANUFACTURE AND INDUSTRIAL VALUE OF ALUMINUM.

BY J. H. J. DAGGER, F.I.C., F.C.S.

It is little over five years ago since I had the pleasure of being present for the first time as a member of this Society, and then listening to a paper read by our esteemed treasurer on what he very truly termed a new departure in metallurgical science—the application of electricity to the reduction of metals from their ores. As in all things new, greater expectations were formed than have been realised; still the electrical furnace then described marked the first step in the production of aluminium at a cost that would place it in the market beside the common metals, and also the raising of electrolytic and electrothermic methods from laboratory and lecture-table experiments to the rank of manufacturing processes. Before passing to a description of some of these, it will be interesting if for a moment I give you in outline the history of this, one of the most beautiful and destined to be most useful of the metals.

History.—Its name is from *Alumen*, the word given by the Romans to all bodies having an astringent taste, hence, alum, which is alluded to by Pliny and Vitruvius as being used as a mordant in producing brilliant dyes. Most probably this was "kahnite," a potash alum which occurs in large quantities in the Solfatara, near Naples, probably formed by the action of volcanic gases on felspathic trachyte. It was not until 1716, however, that Pott first stated the base of alum to be an argillaceous earth, and eight years later Margraff distinguished alumina from lime with which up to that time it had been confounded. In 1807 Davy made an unsuccessful attempt to decompose alumina with the electric current. In 1824 Oersted obtained a grey powder which oxidised rapidly in the air by heating aluminium chloride with potassium amalgam. Three years later, 1827, Wöhler, by decomposing the anhydrous chloride with potassium, obtained a metallic powder which became bright under the burnisher, but it was not until 1845 that he produced the metal in the form of globules large as pin heads. From these he, with infinite patience, determined for the first time the physical characteristics of aluminium. In 1854 Deville and Hansen, working independently, obtained aluminium by electrolysis of the fused chloride, and the same year Deville, substituting sodium for potassium,

obtained the metal in quantity for the first time by the well-known process which, until the recent development of electrolytic methods, has formed the basis of the operations for the production of aluminium at Salindres, and the more recent developments of the industry at Newcastle and Birmingham in our own country. It will perhaps not be forgotten that the first aluminium in this country was produced in 1855 in the laboratory of the Royal School of Mines by Messrs. Dick and Smith, under direction of Dr. Percy, by the action of sodium on eryolite. Gerhard established a factory at Battersea in 1859, and Messrs. Bell Brothers at Newcastle, 1865, produced aluminium by the Deville method, but neither of these undertakings proved successful commercially, and after a time were abandoned. The next stage in the development of the aluminium industry was the improvement and simplifying of the sodium methods by Castner and Netto, both of which processes have been described in the Journals of this Society, as also the well-known Cowles process for production of alloys, which I described at length in a communication to the Society in September 1889.

The advance of electrical science has given us an increased knowledge of the laws of electrolysis, and the improvement in dynamos and electrical machinery has within the last two years reduced the cost of aluminium from 15s. to 5s. per lb. The price of aluminium having fallen from 360s. 1855, 103s. 1857, 62s. 1860, 20s. 1862 to 1887, 15s. 1888, 5s. 1890—91. Any further reduction in price will be rather from improved methods in the production and purification of alumina, for the exceeding difficulty of obtaining the metal free from siliceous and iron has been and still remains an obstacle in the way of its cheap production, greater than we have to deal with in the case of other metals. Although aluminium is one of the most widely distributed of the elements, the necessity of using alumina free from impurities reduces the number of minerals available in our present state of knowledge to very few. These are:—

Bauxite, preferably that from Beaux, in the Department of Var, of which the following are typical analyses:—

	Red.	White.
Al ₂ O ₃	60.73	64.83
Fe ₂ O ₃	20.08	6.65
SiO ₂	3.62	12.60
TiO ₂	1.91	3.44
P ₂ O ₅	0.39	..
H ₂ O	13.27	15.47
	100.00	99.99

Corundum.—Very hard crystalline mineral, sp. gr. 3.909, occurs massive in Northern Georgia, and in India, often as water-worn pebbles in débris from river torrents; here is an analysis of such pebbles from Ceylon and of rock from India, locality unknown:

	Pebbles.	Rock.
Al ₂ O ₃	89.23	84.26
FeO	0.77	..
Fe ₂ O ₃	0.73
SiO ₂	5.55	11.77
TiO ₂	4.88	3.31
CaO	Traces	..
MnO ₂		
	100.43	100.00

Eryolite.—This mineral, a double fluoride of aluminium and sodium, is found in large deposits in one district in Greenland, from which nearly all that is used is obtained; it is found in smaller quantities at Miask in the Ural Mountains, and near Pike's Peak, California. An average analysis of the Greenland mineral is as follows:—

Al	13.23
Na	32.71
F	54.19
Mn ₂ O ₃	0.83

This mineral is not used as a direct source of aluminium, but as a flux in the manner I am about to describe.

Grabau's Process.—Before passing to a description of the electrolytic process for the production of aluminium, I will say a few words about the sodium process as modified by Grabau, of Hanover, in which the difficulties arising from the action of molten alkaline fluorides are overcome in a very ingenious manner, and an aluminium of a high degree of purity is produced. In this process the sodium and aluminium fluoride are heated in two separate iron vessels, the one containing the sodium is provided with a suitable cock for discharging the molten metal, and that containing the fluoride has a drop-bottom, or is fitted with a slide that can be readily drawn. A reducing vessel which is kept cool with a water jacket, and which swings on trunnions, is arranged underneath the two vessels. The aluminium fluoride is heated to a temperature of about 600°, at which it remains pulverent; the sodium is then melted and run into the reducing vessel. When the metal has all run in, the slide is withdrawn and the pulverent fluoride is allowed to fall on to the sodium; the reaction which ensues produces much heat, and the contents rapidly become fluid; the eryolite produced, however, solidifies on the cool sides of the vessel, and the crust thus formed is not attacked by either the fluid eryolite or the aluminium. The aluminium is collected by rapidly shaking the vessel to and fro, and after a minute or two the vessel is tilted and the contents flow into a lower vessel lined with eryolite or aluminium, leaving a crust of solidified eryolite in the reducing vessel. Notwithstanding the very great improvement in the mechanical arrangements and the cheapening of sodium by the recent improvements of Castner and others, it is, I think, only a question of time when the old chemical methods will be superseded altogether by the newer electrolytic processes for the production of aluminium; even at the present time it is not possible to produce aluminium of equal purity by the use of sodium at anything like equal cost. I now come to describe the electrolytic processes in operation on a commercial scale for the production of aluminium. They are, first, the Herault process in operation at the works of the Aluminium Industry Company, Limited, at Lauffen-Venhausen, on the Rhine fall, and those of the Société Electro-Metallurgique at Froges, near Grenoble. In this process the electrolysis is conducted in iron pots or tanks lined with carbon, the pot is raised on insulating supports, and connected with the cable from the dynamo, so that the lining forms the negative electrode, or else this is made of a piece of metal, iron or copper, fixed in the bottom of the pot. The positive electrode is of carbon and so arranged that it can be lowered or raised in the molten charge. The first charge is a small quantity of eryolite, which is rapidly melted by the heat generated by the resistance to the current; as soon as it is fluid the current passes and alumina is fed into the molten flux. The process is continuous and the aluminium which accumulates in the bottom of the pot is tapped every 24 hours. The purity of the metal produced varies from 97 to 99 per cent. During the operation the oxygen combines with the carbon of the positive pole and producing carbonic oxide which burns at the vent in the cover to carbonic acid gas.

At Froges the electric current is supplied by four dynamos, each 6,000 amperes, with a voltage of 15, worked by two large turbines of 300 horse-power each.

At Venhausen are two dynamos constructed to develop 14,000 amperes at 30 volts, and a smaller one of 3,000 amperes at 65 volts. The total horse-power of this plant is about 1,500.

In the Hall process, alumina is dissolved in a fused bath of the double fluoride of aluminium and potassium, or of aluminium and sodium. The salts are mixed in a proportion corresponding to the formula K_2AlF_6 , $(Al_2F_6 \cdot 169 \cdot KF \cdot 116)$. An excess of the potassium salt will increase the solvent power of the bath, but decrease its fusibility. A larger quantity of alumina fluoride renders the bath more fusible, but diminishes the alumina dissolved. The operation is conducted in iron tanks arranged in series. They are lined with carbon, and form the negative electrodes or cathodes. The positive electrodes or anodes are carbon rods, 3 in. diameter, attached by 2-in. copper rods to the conductors or leads by means of suitable clamps. The current of 5,000 amperes and 50 volts in one series, and of 2,000 amperes and 20 volts in the other series is turned on. The mixture of fluorides in the tanks or pots is melted by the heat generated by the resistance they offer to the current. In about two hours' time the mixture becomes fluid, and alumina is added. The resistance of the electrolyte falls

from 15 to about 8 volts, and electrolysis commences, the liberated aluminium sinks to the bottom of the tank, the oxygen going to the positive electrode, combining with the carbon, and escaping as CO_2 . During the operation the bath is kept covered with fine carbon dust, and on this is placed the powdered alumina. When the voltmeter indicates a rising resistance, the attendant stirs in more alumina from the surface of the pot, the carbon dust rises again to the surface, when fresh alumina is placed upon it. The metal produced is dipped out with cast-iron ladles, any entangled electrolyte being skimmed back into the pot. The operation is a continuous one. The metal produced by this process is very pure. The first "run" of metal carries with it all the iron and silicon of the electrolyte, the only remaining sources of impurity being the alumina added, and the ash of the carbons which are consumed in proportion of a little less than weight of carbon to weight of metal produced.

The electrical energy expended is calculated at 22 E.H.P. per hour per lb. of aluminium.

Properties of Aluminium.—The pure metal, free from silicon and iron, is said to be perfectly white, but as produced, it has a bluish-white tinge; when burnished it is exceedingly beautiful; under all ordinary conditions it is attacked upon by air and moisture, sulphuretted hydrogen, ammonium sulphide and cold dilute sulphuric acid have practically no action on it, when free from silicon. The non-corrodibility, however, depends entirely upon the freedom of the metal from silicon and iron. It is not affected by cold nitric acid, and only slowly when heated. The organic acids and salts, as acetates, tartrates, and citrates have practically no corrosive action on it; though in presence of salt action is set up, though very much less than in the case of copper or tin. The salts of aluminium formed are also non-poisonous, and thus would make it valuable for cooking utensils, tins, and cases for preserved foods and meats, &c. Another point in its favour is that following on its high specific heat, it takes much longer for the internal heat to penetrate an aluminium vessel, and so food heated in an aluminium pan would keep warmer for a longer time. If a plate of aluminium be heated and then withdrawn from the fire, it will retain its heat for a sufficient time to cook an egg. Its lightness, too, would make it the ideal metal for travellers' and soldiers' equipments, water bottles, canteens, &c. It would also be most valuable for surgical instruments and tubes.

It is extremely malleable, following after gold in this respect, and may be drawn into fine wire. It can be rolled into sheets about .0007 in. thickness, and drawn, spun, and stamped. It, however, becomes hard by working and requires frequent and careful annealing at low temperatures; the best temperature for working is 100-150° C. Its

hardness equals that of silver. Bars of the metal give a clear musical sound if struck, but the presence of even a small proportion of impurity destroys the resonance.

Castings can be made in ordinary dry sand moulds, gates should be somewhat larger than for brass, but great care should be taken not to heat the aluminium much above the melting point, for otherwise it will absorb gases and become spongy and unsound. The shrinkage is about 2½ per cent. of the length of the mould and ample provision must be made for this in the cores. 100 lb. casting in Al would be equal to 290 Fe, 369 Cu, 280 Sn or Zn, 420 Ag, 48 Pb, 770 Au, 860 Pt.

Aluminium is readily corroded by alkaline solutions forming aluminates, and also by hydrochloric acid and chlorine, and is acted upon more or less by solutions of the chlorides. Very much has been written and said about the properties of aluminium, sensational leaders appear daily in the press, describing wonderful bridges and machinery, ships and houses of the aluminium age, or as one note put at the head of an article, besides which Jules Verne is dull reading, "A Dream of Aluminium." Aluminium is given the most exaggerated properties, and much harm is done to the real value of the metal.

What are the facts, to begin with? Aluminium can never possibly take the place of iron and steel for structural purposes, such as in bridges and heavy machinery; it is not a rigid metal; a bar supported on bearings 24 in. apart was deflected $\frac{1}{4}$ in. with 100 lb. load, $\frac{1}{2}$ in. with 200 lb., and $2\frac{1}{2}$ in. with 300 lb. The permanent set with this load was $\frac{2}{3}$ in., showing the low elasticity; and again, although aluminium is only one-third the weight of iron, it has less than one-half the tensile strength of the best wrought iron, and

only one-third that of mild steel. These facts would prevent it ever replacing these metals in shipbuilding and for structural purposes. But aluminium is beyond all doubt one of the most valuable of metals, and is, I believe, destined to displace almost entirely some of our older metals, for instance, copper, which its superior power in resisting corrosion, its great lightness, will enable it to replace in light machinery and fittings, gas and water fittings, steam pipes, electrical machinery. It would also be invaluable for all art work and decorative purposes. Aluminium plating would supersede both tin and nickel plating; it would largely take the place of tinned ware and German silver and electroplate for table ware. It would also be invaluable to the chemist for many of his laboratory fittings, replacing brass and iron, which corrode so rapidly in such atmospheres. Now, bringing this paper to a close, I regret its imperfect character arising from its being put together amidst presence of other duties. I hope at some future time to bring before you a further account of the development and uses of this valuable and beautiful metal.

DISCUSSION.

The CHAIRMAN, in thanking Mr. Dagger for his valuable paper, invited discussion thereon. He himself would like to know whether aluminium would be of value for making gas pipes and fittings and whether the coal-gas was likely to affect the metal?

Dr. KOHN remarked that in Mr. Dagger's paper there were many points of especial interest to chemists. Personally, he was extremely interested in the details of the electrolytic process itself. They had been told in the description of the method what sort of apparatus was employed and under what conditions the electrolysis was effected. As he understood the process, the alumina is introduced from time to time into a molten flux consisting essentially of the fluorides of sodium (or potassium) and aluminium. He wished to know what percentage of the alumina was obtained as metallic aluminium; whether the reduction was anything approaching the theoretical amount, and also whether the flux remained in its original state at the end of the operation? Did any decomposition of the fluorides take place, and, if so, had any action on the carbon electrodes been noticed, due to the decomposition products of the fluorides? Fluorine might possibly be liberated under these conditions, and since Moissan had prepared two fluorides of carbon, CF_4 and C_2F_4 , it would be of interest to know whether any attacking of the carbon had been observed that might be due to such a decomposition. As to the properties of aluminium, the melting point was stated to be about $1,800^\circ F$. He would be glad to learn at what temperature the metal softened. Platinum began to soften at about $1,400^\circ C$, and this rendered it useless for certain chemical operations at very high temperatures; his object in putting the question was to learn within what temperature limits aluminium could be employed with safety. The importance of aluminium vessels for various operations was one that had always been attractive, and perhaps in the aniline colour industry there might be demands for it. Enamelled iron vessels had so far proved to be the best in most cases for the operations involved; but he presumed, from what Mr. Dagger had told them, that even at 40° to $50^\circ C$, aluminium might be employed with safety in presence of sulphuric acid. He would be glad to know whether this was so. At the same time the flexibility of the metal itself would prevent its being employed otherwise than as a lining to baths or the like. Its application to steam pipes was also a question which might be discussed, and it would be interesting to know whether Mr. Dagger had got results or tried experiments with running water on aluminium pipes, and, if so, whether the pipes corroded at all. In the case of water passing through lead pipes, corrosion increased or decreased according to the nature of the water that passed through them.

Dr. S. G. RAWSON asked what mineral was, on the whole, the most applicable for general use in these different electrolytic processes and furnaces? Bauxite, corundum, and cryolite were all mentioned, and it would be interesting

to know the reasons which caused any one of these to be selected in preference to any other. Corundum, for instance, was purer but dearer than bauxite, would corundum therefore be employed only when a specially pure product was required, or were there other considerations involved, such as fusibility, conductivity, &c.? The electrodes used were of enormous dimensions, up to 3 in. in diameter, were these cut in one solid piece, or built up of prisms? In the former case what material or form of carbon could be taken, for in such large blocks it would be expected that, without some previous form of treatment, the carbon would be soft and porous. The seemingly almost complete insolubility of aluminium in sulphuric acid was very interesting, and Dr. Rawson inquired whether stills for the distillation of sulphuric acid could not be made from this metal. At present both glass and platinum vessels were employed, but there were grave disadvantages attendant upon the use of both these materials, and it seemed possible that these might be removed or lessened by constructing the stills of aluminium.

Mr. KNIGHT asked if it were possible to solder aluminium, as he believed it was somewhat difficult to make joints.

Mr. JONES believed that a small admixture of aluminium had been found to have a beneficial effect in iron castings, as rendering the metal less liable to the presence of blow-holes. In laboratories aluminium would have a great advantage over iron and copper, *e.g.*, in the case of an air-bath. The aluminium air-bath would retain its heat more evenly, and resist better the acid fumes which so soon destroyed copper or iron. He had heard of aluminium being used in making surveyors' instruments, and had been told by an engineer, who had been on the Panama canal, that the difference in weight was most advantageous in that hot climate for those who had to carry the instruments from day to day.

Mr. RHODES inquired whether aluminium could stand the action of weak sulphuric acid; if so, it might be of use for making floats, such as are used in sulphuric acid works, and are of great service in taking measurements.

Mr. DAGGER, replying to Dr. Kohn's question regarding the liberation of fluorine by decomposition of the cryolite, and the part it played in the process, said that in the operation as described no fluorine was liberated. The alumina was decomposed by the electric current, and the action of the fluoride seemed to be merely that of a flux when comparatively small quantities of fluoride were used. If, however, those proportions were departed from, and the pot was allowed to get out of "ore," or alumina ceased to be added in excess, the fluoride would begin to decompose, and that meant the formation of an infusible mass filling up the pot and ending the operation.

In the process conducted by the Pittsburg Co., practically nothing of this kind took place, and the run was continuous. The softening temperature of aluminium would take place between 600° and $700^\circ F$; at that temperature it would begin to get crumbly and work a little. In contact with most other metals aluminium in presence of moisture oxidised. If a plate were taken and bound round with platinum wire alumina would gradually be formed at the contact. In the case of copper and iron vessels, corrosion would take place at the juncture of the two metals. For steam pipes, since the softening of aluminium took place at a low temperature, its action would be uncertain for steam under high pressure, and would therefore not be a reliable metal to use. Out of a yield of 2 lb. of alumina containing 53 per cent. aluminium there would be a loss of about 3 per cent. of the aluminium, so that 97 per cent. of the theoretical amount would be about the yield obtained. Dr. Rawson had asked which would be the best mineral to use in the electric furnace, and he (Mr. Dagger) believed that corundum, if it could be obtained cheap, was certainly the best, having 87 per cent. — 93 per cent. Al_2O_3 ; but for making the alloys he preferred bauxite, as it was easier to obtain and softer. Cryolite was simply used as a flux. It had been found that using cryolite as in the sodium process the quality of metal fell far short and did not repay for the trouble taken. In reply to Dr. Rawson whether bauxite reduced the amount of iron, he

would point out that it was the rule now to prepare alumina from bauxite, and in that case bauxite was a far better mineral to use than corundum, but he would deal with that question at another time. About the carbons, there was rather a difficulty in obtaining them. The great trouble, as a rule, was that they were far too soft. He had found that the best were those which they had obtained from the United States from the mineral oil carbon, and was exceedingly pure, the ash going down to about .01 or .02 per cent. The carbons used were solid, and varied from 1½ in. to 3 in. or 8 in. made in sections, and in plates banded together. Mr. Knight had raised the question as to soldering aluminium. It had not been properly overcome, but he (Mr. Daggar) would give him the formula, which might be of interest to others, and which he had found to give fairly good results. The difficulty in soldering arose of course from the formation of a film of unreducible oxide, which prevented the contact of the solder with the aluminium surfaces. For ordinary work the solder containing Al 6 parts, copper 4, zinc 90, would be used, but the zinc had to be free from iron. For heavy soldering a mixture of Al 12, copper 8, and zinc 80. In reply to Mr. Jones's question, aluminium had a beneficial action on iron in preventing the formation of blow-holes, and in giving sounder castings. Its action was most probably deoxidising and thus enabled it to destroy the oxides and various impurities which were entangled in the molten iron, and which rose to the surface, leaving a much purer and better metal underneath. He had seen it stated that aluminium lowered the melting point of cast iron, and he had himself taken it for granted and stated so in previous papers on aluminium; but from recent observations he rather doubted the statement, although given on high authority. For air baths, the trouble of aluminium softening at 600° was felt, and it was not considered a suitable metal. The action of sulphuric acid on aluminium would be slight at 55° C. In answer to Mr. Norman Tate, the action of coal-gas on aluminium fittings caused no danger, and he could not say that they would be affected to any extent by the impurities contained in ordinary coal-gas, certainly not to the degree to which iron fittings were corroded.

Meeting held at the Societies' Rooms, 207, Bath Street, Glasgow, on Monday, April 6th, 1891.

MR. E. C. C. STANFORD IN THE CHAIR.

ON THE PHYSICAL CONDITIONS EXISTING IN SHALE-DISTILLING RETORTS.

BY F. J. ROWAN, C.E.

THE physical conditions existing in shale retorts have not hitherto been very accurately or minutely observed. A good deal seems to have been taken for granted, and in particular the language generally used with reference to the temperatures employed in shale distillation indicates that it was the prevailing belief that a similar temperature existed inside the retorts to that which was applied to the outside with, at the most, a slight allowance for loss by conduction.

From theoretical considerations Dr. Mills (in his "Manualette of Destructive Distillation," 3rd Ed., p. 15) fixed a definite limit to the temperature required in shale retorts for oil distillation, and he thus discriminated, to some extent, between external and internal temperatures. Dr. Mills says: "Paraffin oil can be prepared from coal, bituminous shale, lignite, wood, peat, Kimmeridge clay, and the like, on the one condition that a very low red heat is employed. It is certain that the greater part of the decomposition and distillation takes place below 427° C. (800° F.). The highest possible boiling point of any normal paraffin is 555° C. (1031° F.) the extreme limit therefore required in a shale retort." (See also *op. cit.* pp. 12-13.)

This, it will be observed, speaks only of the temperature required in shale retorts for the production of paraffins, not of the temperatures actually employed, but subsequent investigation goes to prove, in general, the correctness of the deduction by Dr. Mills. At the same time it must be remarked that the temperature of the boiling point of paraffins is not necessarily the temperature of their formation from organic matter.

In the course of a recent inquiry the author was able to make several series of observations on the actual conditions existing in shale retorts during the process which yields oil and ammonia, and as the results of these observations possess a wider importance than that of the immediate occasion of their being collected, he has been permitted to communicate them to this Society. They were obtained for the most part in the working of the retorts constructed by the Messrs. Armour, of Hermand Oil Works, but they throw some useful light, not merely upon the action of the Hermand retorts, but also upon the course of action in retorts constructed according to other plans, and thus upon the general subject of shale distillation.

It will be well, in the first place, to compare the Hermand retorts with their predecessors, so as to indicate the main features of their design and method of working.

1. The original or "old" vertical retort.

The retort introduced by the late Mr. James Young, F.R.S., about the year 1851, was a cast-iron cylinder, slightly tapered lengthwise, 2 ft. diameter (the section being usually circular but sometimes oval) and 9 to 10 ft. long in the part exposed to heat, with a hopper and drum at the top for charging, and a tray with a water-lute at the bottom for withdrawing the spent shale. Such retorts, which are illustrated in Fig. 1, were usually placed vertically and set in groups of six to one fire or furnace, the flame and fire-gases from which passed to and fro horizontally by three flues or passages, gradually ascending, and thus travelled over the larger part of the exterior surface of the retorts.

The temperature of the exterior of these retorts was kept as high as was consistent with their safety, but frequently reached the point at which the cast iron became soft, when it bulged out or the retort collapsed (or "sat down," as it was sometimes described) by reason of the superincumbent weight of iron and the column of shale. This softening point of cast iron has been fixed at about 1,500 to 1,600° F. (815 to 871° C.), so that these

SESSION 1890-91.

June 1st (Glasgow):—

Dr. E. J. Mills. "Destructive Distillation," Part II.

retorts, containing each its charge of about 10 cwt. of shale, had their lower portions exposed to temperatures ranging from 1,000° F. (538° C.) to 1,500° F. (815° C.) during the

Fig. 1.

OLD VERTICAL RETORT. SMALL SIZE.

12 to 20 hours* which, it is stated, were required to work off a charge. Even under these conditions the oil was usually not fully extracted from the shale.

2. I have been informed that some observations of temperatures which, it is to be regretted, have never been published, were made at Bathgate Works in or about 1870 by Mr. Glen and the works chemist, with a view to determine, if possible, the most favourable working temperatures for retorts of different lengths, and that at these and at Uphall Works the vertical retort was gradually lengthened, first to 12 and then to 15 ft., with the result that an increased yield of both oil and ammonia was obtained, apparently in consequence of exposing the shale for a longer period of time to the action of heat.

Mr. W. Fraser, of the Pumpherston Oil Co., has been kind enough to give me a tracing (Fig. 2), showing the

Fig. 2.

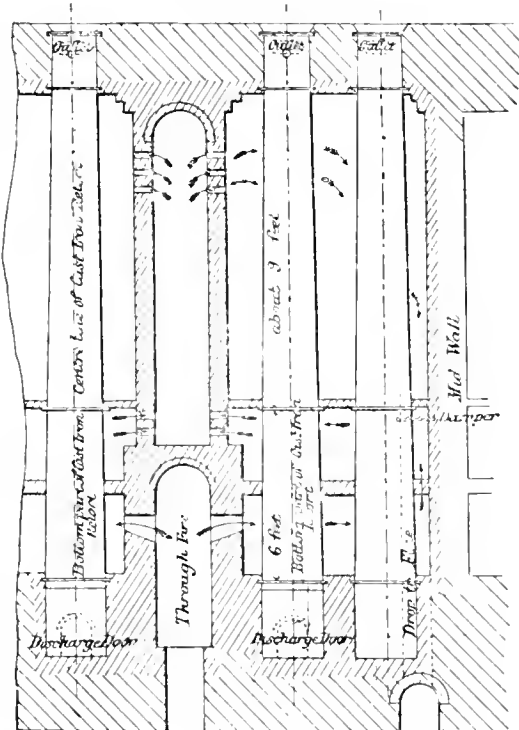

Fig. 2.—continued.

method of construction adopted in the lengthened vertical retorts alluded to, the flues for the fire-gases being so arranged that the lower 6 ft. in length of the retorts were exposed to a higher temperature than the upper lengths of about 9 ft which were heated uniformly. It is also said that longer retorts were used in the old West Calder Oil Works. In addition to these modifications, the records of the Patent Office show that many different forms and sizes of retorts were proposed, but those which were introduced into practical work and have continued in use for any length of time, are, prior to the Armour's retort, the Henderson and the Young and Beilby forms.

Fig. 3.

HENDERSON'S RETORT.

* See G. Beilby, Jour. Soc. of Arts, Vol. XXXIII., p. 315.

3. *The Henderson Retort.*—This retort has been so recently described by Mr. D. R. Stewart (this Journal, 8, 100, 101), that I shall merely refer to the illustration (Fig. 3), and note that it is said to be constructed of

Fig. 4.

YOUNG'S RETORT, 1881.

Fig. 5.

BEILBY'S RETORT, 1881.

cast iron, in length 15 ft. and of oval section $2\frac{1}{2}$ ft. by 1 ft. It contains 18 cwt. of shale, and is worked intermittently, the charge being exposed to heat in the retort for 16 hours, when it is dropped hot into the furnace placed below the retorts. The spent shale is said to contain when thus drawn 12 per cent. of "combustible matter," which I suppose means fixed carbon, and this, with any residual hydrocarbons which it contains, makes it useful for fuel especially as when charged into the furnace it is already

heated to the temperature of combustion. The fire-gases are led up to about half the height of the retorts before being brought into contact with them, and are then made to descend to a chimney flue. The effect of this arrangement no doubt is to maintain the whole of the interior of the "oven" at a uniform temperature.

Mr. Stewart records (in the paper quoted) one or two observations of temperatures obtained during working. He says, "the temperature of the oven is from 900° to 1000° F." (482° to 538° C.); "the steam as it goes into the retort is 630° F." (332° C.); "the shale inside the retort $1\frac{1}{2}$ ft. from the top, three hours after charging 630° F." (332° C.); "16 hours after charging 730° F." (387° C.); "and the products of distillation at the exit pipe 500° to 600° F." (250° to 315° C.).

It is to be regretted that Mr. Stewart did not add some further observations to these, because the shale at the point of observation derives very little heat from the oven and is almost entirely heated up by the highly superheated steam which is introduced at the top of the retort; moreover, any air drawn into the retorts passes in by the hopper lids and tends to keep down the temperature at the top of the retort. Even after 16 hours heating the shale there had acquired a temperature of only 730° F. (387° C.) which is not sufficient for its complete distillation, and if dropped into the furnace in that condition it must have carried some if not most of its hydrocarbons to the fate of being used only as fuel. The products of distillation are taken off at the bottom end of the retort and their temperature is comparatively high. It is probable that in the body of the retort, from the underside of the oven arch to the top of the furnace arch, the shale has the full temperature of $1,000^{\circ}$ to $1,100^{\circ}$ F. (538° to 593° C.).

4. *The Young and Beilby Retort.*—This retort, in its various forms, has also been fully described by both its authors (see especially G. Beilby, Trans. Mining Inst. of Scotland, Vol. V., part 5; this Journal, 3, 216; Jour. Soc. of Arts, Vol. XXXIII., p. 313—325) and is well known.

Figs. 4 and 5 illustrate the steps in design due to Mr. Young (Fig. 4) and Mr. Beilby (Fig. 5) separately; whilst Figs. 6 and 7 show forms of the combined or Young and Beilby retort.

In its most familiar form (Fig. 6) it consists of an iron

Fig. 6.

YOUNG AND BEILBY'S IRON AND BRICK RETORT.

retort, circular or oval in section, and about 9 ft. long, placed upon the top of a fire-brick retort of oblong section about 1 ft. 11 in. by 10 in. at its top end, and 2 ft. 5 in. by 12 in. at the bottom of the straight part, which is 8 ft. long, surrounded by flue passages for flame and heating

gases, and ends in a curved shoot or mouthpiece, about 5 ft. 6 in. in vertical height and tapered to a cast-iron discharging door 15 in. diameter.

Fig. 7.

YOUNG AND BEILBY'S BRICK RETORT.

The cast-iron retorts are grouped above into a series of four by a multiple hopper, which acts as a common reservoir of shale, and is also used to condense the oil vapours so that they may undergo a second volatilisation on being carried back into the retort by means of the green shale. The iron retorts stand in an oven without flues, with openings for inlet and exit of hot gases near the bottom, but on different sides of the oven. The object of this arrangement is stated to be to heat these retorts (or these iron portions of the retort considered as a whole) uniformly to a low red heat, or about 800° F. (427° C.), it being the intention to derive a considerable portion of this heat from highly heated steam and gases passing up inside the retort from the brick portion below. The purpose in having this brick addition to the upper retort is, in the words of its authors, "to treat the residue, or 'spent shale,' to a supplementary operation of steaming after the oil distillation was finished," this supplementary operation being accelerated by the employment of a high temperature (1,832° to 2,000° F. or 1,000° to 1,093° C.) to which the brick retort must be exposed, and which would also enable the red-hot shale coke in it to decompose the steam admitted below and form water-gas. In describing his process, Mr. Beilby said, "The steam entering the lower end of the retort and passing through the red-hot material in the fire-clay portion, is highly superheated and rapidly conveys heat to the raw shale in the upper retort, which is further heated by the flue gases passing outside. The oil vapours and steam passing off by the exit pipe are cooled and condensed, and are collected in tanks. The shale at the lower end of the iron retort receiving the first effect of the highly heated steam, is first exhausted of its hydrocarbons, and the removal of a portion of the materials 'below' moves downwards the whole column within the retort, so that the portion of shale exhausted of its oil products is now brought into the more highly heated clay retort, and being subjected to the current of steam, a large part of its nitrogen is converted into ammonia, which passes away with the steam and oil vapours."*

Ingenious as this process undoubtedly is, and founded upon elaborate and careful analyses and researches carried out by Dr. Grouven and Professor Wm. Foster as well as by Mr. Beilby, yet it is not going too far to assert that its

practical realisation on a commercial scale demands physical conditions which it is extremely difficult, perhaps impossible, to obtain. The labours of Messrs. Young and Beilby have unquestionably resulted in considerable improvement in shale distillation. Operations are directed with more intelligence and care than were formerly the rule, and better results are obtained, but in the foregoing remark I refer to the realisation of the theoretical possibilities of the process.

One of the difficulties was perceived by Mr. Beilby himself soon after commencing to work on a practical scale.

"Spent shale," he says,† "contains about 85 per cent. of mineral ash, consisting of silicates of varying fusibility. As long as the 15 per cent. of fixed carbon (ordinarily contained in the spent shale from simple oil distillation) is intimately mixed with these silicates, the mass is nearly infusible, but whenever any large proportion of the fixed carbon has been burned away by the oxygen of the steam, the ash softens and begins to fuse, and there is the danger that a number of pieces fusing together may plug the retort, and stop the downward passage of the shale. It, unfortunately, happened that the softening point of the ash of the particular shale under consideration was at or near the temperature at which the process could be carried out with economical speed. In the practical working of this shale by the new system, it was evident that the process of burning away the carbon and extracting the nitrogen must be stopped short while there was still sufficient carbon mixed with the ash to keep it from fusing."

Further experience has, however, shown that the difficulty is therein not fully stated, but that the fact is that as soon as the process of distillation is completed the remnant solid materials quickly acquire the temperature necessary to allow them to soften, or that they at once allow the heat inside the brick retort to accumulate, so that the brickwork itself softens, and the mineral matter adhering to it and further aiding to "slag" it, a "gobbed" or plugged retort is the inevitable result. In most oil works the workmen know that to miss a "draw" by a very few hours involves very serious labour on them in order to get the spent shale down.

The results of examinations of internal temperatures obtained at Hermand, and the fact, already stated, that it was necessary to expose the "old vertical" retort to a temperature approaching 1,200° to 1,500° F. in order to extract the major part of the oil from the shale in it, also go to prove that on Messrs. Young and Beilby's system the oil distillation *could not* be finished in the iron retort, so that shale-coke should exist when wanted for the subsequent process in the lower brick retort. The heat of steam and gases passing up from red-hot materials below must also be to some extent delusive, because, if the process were working according to the theory, the *cooling effect* of the decomposition of the steam and the formation of water-gas would be such that all the heat which could be imparted to the brick retort from outside would be required to maintain the inside temperature at the point at which the chemical action was possible. Consequently the resultant water-gas and excess of steam could not be highly superheated, if superheated at all. The actual results obtained in the manufacture of water-gas illustrate this.

5. *The Hermand Retort.*—The retort designed by Messrs. J. and H. Armour, and introduced at the Hermand Oil Works, is comparatively new, and, as far as I know, has not as yet been described to this Society.

At their Breich works, Messrs. Armour made some departure from Messrs. Young and Beilby's designs, and erected retorts (Fig. 8) composed partly of iron and partly of fire-brick, with a special construction of flues for heating, and without multiple hoppers, but of a greater length than the ordinary Young and Beilby design.

The Hermand retort, however (Fig. 9), is different from any other vertical retort which has been hitherto worked. It is built entirely of fire-brick, in section is rectangular and tapered from 1 ft. 6 in. by 1 ft. 3 in. at the top just under a cast-iron hopper, to 3 ft. 6 in. by 1 ft. 6 in. at

* Jour. Soc. Arts, Vol. XXXIII., p. 516.

† Jour. Soc. Arts, Vol. XXXIII., p. 518.

the bottom of the straight shaft, which is 22 ft. long. The straight shaft terminates in a curved shoot, which tapers down to a circular cast-iron discharging door of ordinary pattern, 5 ft. in vertical height below the bottom of the straight part, this shoot having a capacity of 30 cub. ft., and constituting a cooling chamber, as no heat is applied to it outside. Steam is admitted to the retort in this shoot by a pipe inserted about 12 in. above the discharging door,

Fig. 8.

ARMOUR'S BRITISH RETORT.

and this aids the cooling of the spent shale. It is certain, however, that some air enters continually by the door and brickwork, and this air seems to supply oxygen for the combustion of some of the carbon of the shale, and thus to raise a portion of it to a red heat at about the top of the curved portion at the back where the steam does not penetrate. On the top of the straight shaft is placed a

Fig. 9.

ARMOUR'S HERMAND RETORT.

cast-iron hopper, 4 ft. deep, of oval section 3 ft. 2 in. by 1 ft. 11 in., the exit pipe for the oil-gases being placed at the bottom of the hopper.

The capacity of the Hermand retort, as compared with the Young and Beilby or "Pentland" retort is as follows:—

HERMAND RETORT.

	Cub. Ft.	Tons Cwt.
Hopper.....	15½	0 6½
Retort body	92	2 1
Curved shoot or cooling chamber	30	0 13½
	137½	3 1½

YOUNG AND BEILBY RETORT.

	Cub. Ft.	Tons Cwt.
One quarter of multiple hopper	25	0 10
Upper retort (iron)	20½	0 9½
Lower retort (brick)	24	0 10½
Curved shoot or cooling chamber	22½	0 10½
	92	1 10½

These weights are found by taking the shale as equal to 50 lb. weight per cubic foot in the broken state, some actual trials with a box of 4 cub. ft. capacity having given a mean of 49 lb. per cubic foot.

The heating of the Hermand retort is carried out exclusively by the combustion of the scrubbed gas, which is introduced by a pipe near the bottom of the straight shaft. The flame and fire gases are conducted round each group of four retorts by a continuously ascending spiral flue, which forms six steps or stages in the vertical height of the retort. On reaching the end of their travel (of 211 lineal feet) in the top ring of the spiral, the hot gases ascend into a flue which runs along the full length of a bench of retorts on the exit or outside of the hoppers. The two outside flues of a bench unite at one end in a central flue, in which the inner sides of the hoppers are exposed to the hot gases, and thence to the chimney which is placed at the end of each bench of retorts. By this arrangement there is a very complete and economical utilisation and distribution of heat, the temperature gradually diminishing as the fire-gases ascend, the last portions being made use of to heat up the fresh charges of green shale in the hoppers, so that very little is lost in waste gases escaping to the chimney. The total amount of heating surface exposed to the flame and fire-gases is 254 sq. ft. in these retorts, as against 124 sq. ft. in the Young and Beilby form.

These details are important, because they are witness to the presence of several elements which render these retorts specially suitable for the examination of temperatures under the most favourable conditions. The shale is heated up before it enters the retort body, and as it descends the temperature surrounding the retort is gradually increased as the chemical action tends to become less vigorous. No extraneous heat is supplied to the shale by means of superheated steam, as only exhaust or "soft" steam is admitted to the retorts; and, finally, there is no cooling of the escaping oil vapours by reason of contact with cold shale or hopper or other surfaces.

Temperatures in Flues.—A series of measurements of the temperatures in five of the stages of the spiral flue (commencing at the lowest one), taken by means of the Siemens copper ball pyrometer, gave the following results:

1st or lowest stage of flue, 1550° F.

At the next test here the copper ball was melted in consequence of its being placed in the flame.

2nd stage of flue, 1340° F.

Three tests here gave exactly the same result.

3rd stage of flue, (a) 1050°, (b) 1125°, (c), 1125°.

4th stage of flue, (a) 990°, (b), 1070°.

5th stage of flue, (a) 930°, (b) 930°.

The same stage at the next adjoining retort was taken subsequently for a test, because the opening of spy-holes in the lower flues of the one hitherto examined had cooled the upper portion of it considerably. This 5th stage of flue gave (a) 1060° and (b) 1000°.

These temperatures are shown in black figures on the sections, Figs. 10 and 11.

Fig. 10.

These readings are, of course, only approximations to the actual temperatures, this being all that instrument can afford, and it is to be remarked, moreover, that they were taken at the time when the retorts were being drawn below and freshly charged above, so that there would be found consequently the greatest amount of difference between the top and bottom temperatures which these retorts could exhibit in working.

On another occasion, when observations of the internal temperature were being taken by Mr. Harry Armour, simultaneous tests of the temperature in these external flues were made by me with one of Murrie's pyrometers having a scale of 1000° to 2000° F., but not reliable beyond 1950°. This instrument showed in the third stage of flue from bottom 1900° F., and the pyrometer index was moving up rapidly beyond that figure when the instrument was withdrawn to avoid damaging it; in the fourth stage of flue, 1510° F.; and in the fifth stage of flue, 1250° F. These temperatures are shown in the outside row of the figures on the right of section, Fig. 11.

By means of another instrument of the same kind, but having a lower range, the temperature in the side flues on the top of the retort benches was found on different occasions to be 770° F., 895° F., and 910° F., the first reading having been taken while the bench was being

charged with cold shale. The central flue leading to the chimney and at 41 ft. and 10 ft. distance from the chimney showed 640° F., 650° F., and 648° F.

Fig. 11.

Temperature of Shale in Hoppers.—In order to ascertain the temperature of the shale in the hoppers at different periods a Murrie's pyrometer having a range of from 300° F. to 900° F. was used. The stem of this instrument was 5 ft. 6 in. long, but the bulb or mercury chamber was 9 in. from the bottom end. On one occasion it was inserted into the shale in a hopper just after a draw and before fresh shale was charged. The pyrometer stem extended 4 ft. 3 in. down from the hopper lid, and was left for half an hour, when the reading was 480° F. On another occasion the same instrument was placed in the midst of a charge of green shale at 11.30 a.m. and allowed to remain in the shale till 8.45 p.m., dropping down to its full extent when the charge dropped.

At first only 3 ft. of the stem were inside the hopper, and there was no indication on the dial till 1.15 p.m., when the index showed 320°, although the hopper itself was very hot during the whole time. The pyrometer dropped down to its full length with the charge at 2.35 p.m., when the draw took place and the temperature became 350° F. (177° C.). A fresh charge being put into the hopper the temperature fell to 320° F. (160° C.).

8.0 p.m. " "	720	(382)
8.40 p.m. " "	750	(399)

8.45 p.m. the charge was drawn and the pyrometer tilted against the side of the retort. This caused the index to rise quickly, and as it touched the limit of the scale the instrument was withdrawn. The shale at this point, just entering the body of the retort, was found to be hotter than the escaping oil vapours, but not hot enough for distillation. In fact, subsequent tests showed that the shale does not reach a temperature of 1000° F. until it is about 6 ft. from the top of the retort.

Temperature of Shale in the Retort.—A pyrometer (Murrice's) having a range of 1000 to 1800° F., the length of stem being 18 ft. 2½ in. was inserted to a depth of about 10 ft. at 10.50 a.m. when charging retorts. Its position is shown at P on Fig. 10.

At 4.35 p.m. the first movement of the index gave 1020° F.

During these tests an experiment, which had been previously carried out on different occasions by me and by Professor Foster and Mr. A. H. Allen, was repeated by Mr. Harry Armour in my presence. The object of it was to ascertain the condition of the shale at the bottom of the retort, beyond the point to which the pyrometer stem reached.

In addition to the usual "draw" of half a hutch-load from a retort, another half or three-fourths of a hutch was drawn, and a portion of this last draw was transferred while hot, smoking and blazing, to a small experimental retort placed alongside and ready heated. A lid was put on and a steam jet turned into this small retort, and very soon a stream of oil and ammonia water was collected from the end of the iron pipe which did duty as a condenser. I have specimens of these products here and they, with the cloud of black dust, consisting of particles of unconsumed carbon, which accompanies every draw that I have witnessed at Hermand, Breich, Pumphreaston, Holmes, or other works, are irrefutable witnesses to the fact that the temperature inside to the bottom of these retorts, except in rare instances, does not exceed 1100 to 1150° F.

Temperature of the Escaping Oil Vapours.—By means of a glass mercury thermometer inserted at T. (Fig. 10) in the exit pipe where it issues from the brickwork of the bench, a continuous series of readings of the temperature of the escaping oil vapours during 12 hours was obtained. Various other observations were made from time to time which are not quoted here, as they are merely confirmatory of this series:—

At	F.
6.30 a.m. the thermometer was inserted.	
7.30 a.m. the temperature was	450
8.30 a.m. " "	469
9.0 a.m. a draw took place and the retorts were freshly charged.	
9.20 a.m. the temperature was	220
9.30 a.m. " "	320
10.30 a.m. " "	369
11.0 a.m. " "	376
11.30 a.m. " "	400

At	° F.
12 noon the temperature was	416
12.30 p.m. " "	417
1.0 p.m. " "	450
1.30 p.m. " "	455
(Draw and fresh charge took place).	
1.40 p.m. the temperature was	284
2.0 p.m. " "	295
2.30 p.m. " "	304
3.0 p.m. " "	321
3.30 p.m. " "	333
4.0 p.m. " "	353
4.30 p.m. " "	362
5.0 p.m. " "	378
5.30 p.m. " "	392
6.0 p.m. " "	400
6.30 p.m. " "	410

The regular fall of temperature in both shale and escaping oil vapours at the period of a draw and a fresh charge is not due to any contact with cold shale, but, as it appears to me, to the dropping of shale more highly charged with hydrocarbons into a hotter region, which causes the instantaneous production of a larger volume of gases with the accompanying cooling effect.

Although the comparatively high temperature of 1,200° F. (650° C.) was twice recorded during the examinations of the internal temperature of the retorts, I do not think that it necessarily follows that all the shale had then reached that temperature. This opinion is supported by the fact that on a draw taking place in both the instances referred to the pyrometer descended along with the shale into a hotter region in the retort, and yet the temperature simultaneously suffered a considerable fall which was maintained.

It appears to me that this occasional and temporary rise of temperature is due to the thermometer being for the time surrounded by pieces of shale which had become more quickly exhausted of their hydrocarbon constituents, and had in consequence been able to retain more heat in a sensible form. No one who has watched the operation of drawing retorts can have failed to notice that there are always some pieces of shale which are hotter than others, and this result is undoubtedly due, in great part, if not wholly, to the difference in chemical constitution to which I refer. Some pieces of shale are undeniably much richer in hydrocarbons than others, and they therefore require a longer application of heat for their complete resolution. It is easy to understand, therefore, that if some of the poorer pieces were left surrounding the pyrometer for some hours, they would, on becoming exhausted of oil-yielding constituents, be at once able to retain heat, and would become much hotter than surrounding pieces in which the process of decomposition was still going on. The pyrometer would record this state of matters until the dropping of the charge brought it clear of such exceptional circumstances and into contact with shale which showed more accurately the average temperature of the mass.

I have omitted to state above that during the course of the observations of temperature which are recorded in this paper, the specific gravity of the crude oil produced from day to day was found to remain about 0.873 to 0.878, the temperature being 102° to 120° F.

Analysis of Permanent Gas.—Another indication of the moderate temperature existing in the retorts is found in the chemical constitution of the permanent gas. The following analyses were made (I.) by Mr. R. R. Tatlock, of Glasgow, and (II.) by Professor W. Foster, of London, from samples taken by them at different times from the gas main at Hermand.

ANALYSIS I.

	Per Cent.
Carbonic acid	23.0
Carbonic oxide	4.0
Hydrogen	13.4
Olefines	1.6
Marsh-gas	19.7
Oxygen	1.3
Nitrogen	37.0
	<hr/> 100.0

ANALYSIS II.

	Per Cent.
Carbonic acid	20.7
Carbonic oxide	1.16
Free hydrogen	21.68
Heavy hydrocarbons, ethylene, &c.	1.6
Marsh-gas	8.66
Free oxygen	3.6
Free nitrogen	42.6
	<hr/> 100.0

The proportions of carbonic acid to carbonic oxide in these analyses show that the temperature in the retorts must have been a long way below 1,472° F. (800° C.), which is the lowest temperature at which the reactions resulting in the formation of water-gas take place. By "water-gas" I mean the mixture of gases produced by the decomposition of steam by carbon at the temperature which causes that mixture to contain the largest proportion of carbonic oxide and the smallest proportion of carbonic acid possible.

These analyses also confirm a statement which was made to me by Mr. N. M. Henderson of Broxburn Oil Works, before the analyses were made, viz., that more than half the volume of permanent gas obtained from retorts constructed of brickwork, or partly of brick and partly of iron, and worked at a pressure slightly lower than that of the atmosphere (in consequence of the use of exhausters for drawing off the oil gases from the retorts and mains) consists of atmospheric air which has been drawn in partly through the retorts and partly into the pipes without passing through the hot portions of the retort.

A survey of these results conduces to the conclusion that they offer a very plain confirmation of the chemical or physical law, that change of physical condition, from solid to liquid or from either to gas, is invariably accompanied by absorption of heat, or the production of what is called "latent heat;" and they also illustrate the fact that as long as such a process is in operation it is practically impossible that there can be any considerable increase of sensible heat.

I have heard these things denied or ignorantly described as "physical impossibilities;" but the every-day example of the action of boiling water for the production of steam is a witness at once of their truth and of the ignorance of the objection. It is well known that not only does an immense amount of sensible heat disappear and become latent in the effort to effect the change in the physical state of water from the liquid to the gaseous, but also that as long as water in the liquid form remains in the vessel to which heat is being applied, it does not matter what external temperature is applied, or what is the conductivity of the material of the vessel, the temperature of the water steadily and persistently refuses to advance beyond 212° F. The moment however that the last drop of water disappears the possibility of accumulating sensible heat in the steam appears and is limited only by the period at which dissociation causes the destruction of that gaseous body by its resolution into its elements. The case of shale distillation is strictly analogous, and it will certainly not be to the disadvantage of the process if such physical laws are recognised in the methods by which it is carried out.

Meeting held in the Philosophical Institution, Edinburgh,
on Tuesday, May 5th, 1891.

MR. E. C. C. STANFORD IN THE CHAIR.

ON THE DIRECT ESTIMATION OF ARSENIC IN MINERALS, METALS, &c.

BY JOHN CLARK, PH.D., &c.

In a provisional specification "For decomposing sulphides of copper, &c.," taken out by myself in conjunction with Mr. Alexander Esilman in 1867, it was pointed out for the first time that the persalts of iron decomposed the sulphides of a large number of metals, separating sulphur and forming a salt of the metal which was accompanied by the reduction of the ferric salt employed to the corresponding ferrous salt. It occurred to me that this action of the persalts of iron on sulphides might be utilised for the estimation of arsenic when in the form of sulphide. For this purpose known quantities of pure sulphide of arsenic were distilled with a concentrated solution of ferric chloride in strong hydrochloric acid in an ordinary flask connected with a worm condenser, to the end of which a wide tube was attached, which dipped into pure water. The arsenic was then precipitated with sulphuretted hydrogen in the cold and collected on a weighed filter with the following results:—

	Per Cent.
(1) 5 grs. As_2S_3 gave.....	5.02 = 100.40
(2) 5 grs. As_2S_3 gave.....	4.95 = 99.00

It is absolutely necessary, in estimating the arsenic in this way, that the HCl should be concentrated, and it is always advisable to evaporate down the solution three times with a considerable quantity of strong HCl. The perchloride of iron decomposes the H_2S , which would be produced by dissolving the As_2S_3 in HCl, facilitates the solution, and enables the arsenic to be estimated direct.

When the As_2S_3 is dissolved in strong HCl without Fe_2Cl_6 , As_2S_3 condenses in the tubes of the apparatus, owing to the evolution of H_2S along with the chloride of arsenic.

Ferric sulphate also decomposes sulphide of arsenic in presence of moderately concentrated sulphuric acid, but the decomposition is much more difficult and seldom perfect.

I have made a number of experiments with ferric chloride on mixed sulphides of arsenic, antimony, and tin with the most satisfactory results, and I have found this to be the simplest and most reliable process for the estimation of arsenic in antimony ore. It is also applicable for the direct estimation of arsenic in iron and copper pyrites, but the ore requires to be very finely ground, a large excess of ferric chloride used, and the evaporation carried down pretty far. When, however, the distillation is carried too far, the distillate is apt to contain a little free sulphur and smell of sulphurous acid, due to the formation of a little chloride of sulphur and its subsequent decomposition by the water in the receiver into HCl, S, and hyposulphurous acid, which, in its turn, is resolved into sulphurous acid and free sulphur. It is, therefore, advisable when the distillate shows any appearance of sulphur to dilute it with water sufficiently to prevent the volatilisation of chloride of arsenic, boil to expel the sulphurous acid, filter if necessary, and then precipitate the arsenic with H_2S in the usual way. A sample of pyrites in which 1.19 per cent. of arsenic was found in the usual way gave, when distilled with ferric chloride, 1.26 and 1.31 per cent.

The perchloride of iron can also be used for the estimation of arsenic in natural arsenides, such as Kupfer nickel, smaltine, &c.; thus:—

Ten grs. arsenide of Ni with Fe_2Cl_6 and HCl gave 40.6 As. The same mineral gave, after oxidation by the usual method, 40.43 per cent. of arsenic.

In the case of the native arsenide of cobalt or smaltine the decomposition is rather more difficult, but when the mineral is finely ground and a large excess of Fe_2Cl_6 employed the mineral is completely decomposed, and the results obtained are very satisfactory.

Ten grs. of a smaltine, which by the ordinary oxidation process was found to contain 52.50 As per cent., gave by distillation with Fe_2Cl_6 and HCl—

1st experiment...	8.57 of As_2S_3 = 52.25 per cent. of As.
2nd experiment...	8.64 of As_2S_3 = 52.68 per cent. of As.

On a former occasion I showed to the Society that perchloride of iron could be used in the estimation of the smallest quantities of arsenic in copper. It is, of course, equally suitable for the estimation of arsenic in brass and bronze, and in my opinion it might, with advantage, be tacked on to Reinsch's process in the estimation of arsenic in cases of poisoning and in organic mixtures containing only a small quantity of arsenic. Reinsch's process is one of the simplest and most reliable methods for the detection of arsenic, and the whole of the arsenic is deposited on the copper when sufficient time is allowed. H. Carmichael (American Jour. 1886, 129) estimates arsenic quantitatively by ascertaining the number of pieces of copper of a certain size which are coated steel-grey with the arsenic, but in my opinion it is more satisfactory to obtain the arsenic in a form in which it can be weighed. This can easily be done by distilling the coated copper with ferric chloride and HCl. In carrying out the process the stomach or material under examination is boiled gently with dilute HCl and pieces of pure copper foil. As soon as one piece has become decidedly coated it is taken out, washed with a little alcohol to remove any adhering fat, and dropped into the distillation flask. The washing with alcohol is very important, as otherwise fat, which is generally present in such cases, adheres to the copper and makes its appearance again along with the arsenic in the distillate. When the material no longer affects the copper after boiling for 20 minutes, the whole of the pieces are distilled with HCl and Fe_2Cl_6 in the usual way. It is, of course, absolutely necessary in a case of poisoning to make a blank experiment with the same quantity of the copper foil.

The experiments made to test the accuracy of this process gave very good results. Thus—

0.2 gr. As_2O_3 put into an organic mixture containing a good deal of fat gave 0.215 As_2S_3 = 0.197 grain of As_2O_3
0.1 grain of As_2O_3 gave 0.105 As_2S_3 = 0.084 grain of As_2O_3
0.05 grain of As_2O_3 gave 0.05 As_2S_3 = 0.040 grain of As_2O_3

When zinc containing arsenic is dissolved in ferric chloride or ferric sulphate a portion of the arsenic is given off in the form of AsH_3 ; in fact, in the case of some arsenides of zinc made by myself, containing from 5 to 10 per cent. of arsenic, the loss in this way amounted to from 10 to 20 per cent. of the whole, and even when the arsenide was dissolved in pure iron alum a little AsH_3 was evolved. This could be prevented by dissolving the zinc in a mixture of ferric sulphate and sulphate of silver, and distilling off the arsenic with HCl, but the easiest way is to dissolve in dilute H_2SO_4 and pass the gas through a solution of sulphate of silver, which decomposes the AsH_3 , then filter off the precipitated silver and mix the filtrate containing the arsenic with the undissolved residue from the zinc, and distil with Fe_2Cl_6 and HCl.

Small quantities of arsenic are occasionally found in iron, as practically all the arsenic in iron ores goes into the pig iron, and when this is dissolved in dilute H_2SO_4 or HCl, according to Pattinson and Stead, all the arsenic is left behind as black, insoluble arsenide of iron. In this case the arsenic can easily be determined by distilling the residue with ferric chloride and strong HCl. In the experiments which I made I found that in pig iron at any rate a portion of the arsenic is evolved as AsH_3 when it is dissolved in dilute H_2SO_4 and it is therefore always advisable to pass the H which is evolved through a solution of sulphate of silver to get the whole of the arsenic. Thus, a sample of pig iron containing arsenic, when dissolved in dilute H_2SO_4 gave the following results:—

	Per Cent.
Arsenic evolved as AsH_3	0.073
Arsenic insoluble in dilute H_2SO_4 ..	0.092
Total.....	0.165

In determining phosphorus in iron in presence of arsenic by the molybdic process, the precipitate is apt to contain

arsenic, and this can be most conveniently estimated, in my opinion, in the magnesia precipitate by distilling with HCl and ferrous chloride. It has been pointed out by Reis that when arsenic is estimated by the molybdic process the arsenic precipitate separates very slowly at a temperature of from 40° to 50° C., at least 24 hours being necessary for the purpose. I have found that the phosphorus is precipitated before the arsenic, and when the temperature is not allowed to rise beyond 40° C. and the precipitate is filtered off within two hours of precipitation, it is quite free from arsenic, even when a considerable quantity of arsenic acid is present. Even at a temperature of 85° C. only a small percentage (about 5 per cent.) of the arsenic is precipitated in the course of three or four hours, so that I am of opinion that the presence of arsenic in pig iron does not interfere with the estimation of the phosphorus by the molybdic process to the extent which is generally believed.

AN ACCOUNT OF THE MANUFACTURE OF PHOSPHORS.

BY J. B. READMAN, D.Sc., F.R.S.E., F.C.S., EDINBURGH.

PART III.

In my last paper on the manufacture of phosphorus, read before this Society about a year ago, I referred to experiments that I had made with the view of cheapening the process for producing phosphorus, by dispensing altogether both with the use of sulphuric acid to decompose the phosphate of lime and also with the employment of fireclay retorts for distilling the desiccated mixture of phosphoric acid and carbon.

The preliminary experiments, some of which were given in detail in that paper, proved conclusively that silica in the form of sand, ganister, flints, &c., intimately mixed with phosphate of lime and carbon in suitable proportions, was capable, at a high temperature, of expelling practically all the phosphorus contained in the mixture, and that with adequate condensing appliances a very large proportion of the phosphorus may be collected.

Since then a large number of additional experiments have been made to ascertain if it is essential to employ as the raw material, or source of phosphorus, one or other of the native phosphates of lime that are imported in vast quantities into this country from the United States and Canada, France, Spain, Belgium, Norway, &c., &c., for the manufacture of superphosphates, or, if native phosphate of alumina, such as that known as "Redonda" phosphate, would be available.

Experiment proved that with suitable fluxes the latter class of phosphates may be advantageously employed for producing phosphorus, satisfactory results having been obtained from them as well as from phosphate of lime.

So much for the successful solution of the first part of the investigation, viz., the substitution of silica for sulphuric acid in the decomposition of the native phosphate, but the second part, viz., to obtain a suitable apparatus wherein to conduct the distillation, presented many difficulties. Retorts were found unsuitable both on the score of economy and durability, and as the blast furnace seemed likely to be successful, I resolved to give it a fair trial.

I need not take up time by going much into detail in describing the experiments, which were conducted on a large scale for several months. Suffice it to say that this style of furnace was found to be unavailable for the purpose. The large volume of air required, and the difficulty, or perhaps impossibility, of driving off the phosphorus by the time the phosphorus-bearing mixture passed the tuyeres of the furnace, were serious obstacles to success. All the air that was passed into the furnace produced gases which had to be cooled and dealt with when they left, for they contained all the phosphorus that was expelled from the material. Then again the slag passing the hottest part of furnace and yet retaining much material only partially

decomposed, rendered the former highly infusible and difficult to tap, and sooner or later caused "scaffolding" and choking of the furnace.

Various sizes and shapes of blast furnace were tried, and the blast was used both cold and highly heated, with little pressure and at a pressure of several pounds to square inch; water-jacketed and brick-lined furnaces were tried in turn, but the difficulties indicated, and other experiments in course of working, were found to be insurmountable, and this form of furnace had to be abandoned.

The success of the application of electricity to the production of certain metals and alloys led me to try this source of energy on the manufacture of phosphorus. The results of the first series of experiments were so encouraging, that provisional protection was taken out on 18th October 1888, for the preparation of phosphorus by its means.

The trials were carried on at this time on a very small scale, the power at my disposal being very limited in amount, yet the elements of success appeared to me so great, and the decomposition of the phosphorus-bearing material was so complete, that I resolved to prosecute the process on a large scale. After a good deal of negotiation with several firms who were in a position to supply the electric energy required, I finally made arrangements with the Directors of the Cowles Co., Limited, of Milton, near Stoke-on-Trent, the well known manufacturers of alloys of aluminum, for a lease of a portion of their works and for the use of the entire electrical energy they produced for certain portions of the day.

The plant at these works has been frequently described, both at the meetings of the British Association and at other societies of a like nature, and are in all probability familiar to some of the members present. The following is an abridged description of the works and plant as given before Section G* of the British Association:—

The works were built near the Milton Station, on the North Staffordshire Railway, the boilers for generating the steam required are of the Babcock-Wilcox type and are provided with mechanical stokers; the steam engine is of 600 h.p., and is a compound, condensing, horizontal tandem, made by Messrs. Pollit and Wiggel, of Sowerby Bridge. The fly wheel of this engine is 20 ft. in diameter and weighs 30 tons, and is geared to the pulley of the dynamo, so that the latter makes five revolutions for each revolution of the engine by rope driving gear, consisting of 18 ropes. The engine is an extremely fine specimen of a modern steam engine, it works so silently that a visitor standing in the engine room with his back to the engine railings at the time the engine is being started cannot tell whether it is in motion or not. In regard to the dynamo, the spindle is of steel, 18 ft. long with three bearings, one being placed on either side of the driving pulley. The diameter is 7 in. in the bearings and 10 in. in the part within the core. This part in the original forgings was 14 in. diameter and was planed longitudinally so as to leave four projecting ribs or radial bars on to which the core discs are driven, each disc having four key ways corresponding to these ribs. There are about 900 of the discs, the external diameter being 20 in., and the total length of the core 36 in.

The armature winding consists of 128 copper bars, each $\frac{7}{8}$ in. deep, measured radially, by $\frac{3}{4}$ in. wide. These 128 bars are coupled up so as to form 32 conductors only; this arrangement has been adopted to avoid the beating from the Foucault currents, which with $1\frac{1}{2}$ in. conductors would have been very considerable. The bars are coupled at the ends of the core across a certain chord and are insulated.

The commutator is 20 in. long and has 64 parts. The current is collected by eight brushes mounted on a separate ring, placed concentric to the commutator and the current is led away from these brushes by a large number of thin bands of sheet copper strapped together into convenient groups. The field magnets are of the horizontal double type.

As this machine is virtually a series wound machine, the magnet coils each consist of a few turns only of forged copper bars, $1\frac{1}{2}$ in. wide \times 1 in. thick, forged to fit the magnet cores.

There is no insulation other than mica wedges to keep the bars from touching the core.

Another account states that the dynamo furnishes a current of about 5,900 amperes, with an E.M.F. of 50 to 60 volts, and is said to be (1888) the largest machine (at least in regard to quantity of current) in England, and probably in the world.

The current from the dynamo is led by copper bars to an enormous "cut-out" calculated to fuse at 8,000 amperes. This is probably the largest ever designed, and consists of a framework carrying 12 lead plates, each $3\frac{1}{2}$ in. \times $\frac{1}{16}$ in. thick. A current indicator is inserted in the circuit consisting of a solenoid of nine turns. The range of this indicator is such that the centre circle of $360^\circ = 8,000$ amperes.

The electrodes consist of a bundle of nine carbons, each $2\frac{1}{2}$ in. diameter, attached by casting into a head of cast iron. Each carbon weighs 20 lb., and when new are about 48 in. long. I have here specimens of these carbons.

The "head" of the electrode is screwed to the copper rods or "leads," which can be readily connected with the flexible cables supplying the current.

The electric furnaces are rectangular troughs built of fire-brick, their internal dimensions being 60 in. \times 20 in. \times 36 in. deep. Into each end is built a cast-iron tube, through which the carbon electrodes enter the furnace.

The large sketch exhibited on the wall will show the general arrangements of the furnace and carbons.

The electrodes are so arranged that it is possible by means of a screw arrangement to advance or withdraw them from the furnace.

It is here necessary to remark that the whole current generated by this vast dynamo is passed through one furnace, such as has been described.

In these experiments, in Staffordshire and elsewhere, we worked entirely with raw materials, for it was evident it was only by the direct production of phosphorus from the native minerals that contain it, such as phosphates of lime, magnesia, or alumina, that there was any hope of superseding, in point of economy, the existing process of manufacture.

In the furnaces as used at Milton we experienced much difficulty in distributing the heat over a sufficiently wide area. So locally intense indeed was the heat within a certain zone that all the oxygen contained in the mixture was expelled, and alloys of iron, aluminium, and calcium, combined with more or less silicon and phosphorus, were produced. Some of these were of an extremely interesting nature, and may form the subject of a further communication to the Society.

The experiments on the large scale had not advanced very far when I became aware that another application for letters patent for producing phosphorus had been made by Mr. Thomas Parker, the well-known practical electrician of Wolverhampton, and his chemist, Mr. A. E. Robinson. The joint patent is dated 5th December 1888, and was thus applied for only seven weeks after my application was lodged.

It appeared that Mr. Parker had conducted a large number of experiments simultaneously, but quite independently, of those carried on by myself and those who assisted me, and that he was quite unaware—as I was unaware—of any other worker in this field. It was no small surprise, therefore, to find, during our interview, which took place some time after the dates referred to, that the two patents were on practically the same lines—viz., the production of phosphorus by electricity.

Our interests lay so much together that, after some delay, we arranged to jointly work out the process, and the result has been the formation of a preliminary company and the erection of a large-scale experimental plant in the neighbourhood of Wolverhampton, to prove the commercial success of the new system of manufacture.

The following is a short account of the works and plant at that place:—

The ground is situated on the banks of a canal, and extends to about 10 acres, which are wholly without buildings, except what have just been erected for the purposes of the experiment. These consist of boiler and engine-houses and large furnace sheds.

There are three Babcock and Wilcox steam-boilers of 160 h.p. each, and each capable of evaporating 5,000 lb. of water per hour. The water tubes are 18 ft. long \times 4 in. diameter, and the steam and water drums 42 in. diameter and 23 $\frac{1}{2}$ ft. long, of steel $\frac{7}{16}$ in. thick, provided with a double dead-weight safety-valve, stop-valves, blow-off cock, water-gauges, and steam-gauge.

The total heating surface on each boiler is 1,619 sq. ft., and the total grate surface 30 sq. ft.

The boilers are worked at 160 lb. pressure.

The engine is a triple compound one of the type supplied for torpedo boats, and built by the Yarrow Shipbuilding Company. It is fitted with a Pickering governor for constant speed. The engine is capable of delivering (with condenser) 1,200 I.H.P., and without condenser, 250 I.H.P. less. With steam at 170 lb. pressure the engine worked at 350 revolutions per minute, but it has been re-arranged so as to deliver 700 I.H.P. with 160 lb. steam pressure, without condenser, and at 300 revolutions per minute—

The high-pressure cylinder is 14 $\frac{1}{2}$ in. diameter.

The intermediate " " 25 in. " "

The low-pressure " " 32 in. " "

The stroke is 16 in.

The dynamo for producing the requisite amount of electrical current supplied to the furnaces is one of the well-known Elwell-Parker type of alternating current dynamos designed to give 400 units of electrical energy, equivalent to 536 I.H.P.

The armature in the machine is stationary, with double insulation between the armature coils and the core, and also between the core and the frame, and is so arranged that its two halves may be readily connected in series or in parallel in accordance with the requirements of the furnaces, e.g., at an electro-motive force of 80 volts it will give 5,000 amperes, and at 160 volts, 2,500 amperes when running at 300 revolutions per minute.

The exciting current of the alternator is produced by an Elwell-Parker shunt-wound machine driven direct from a pulley on the alternator shaft and so arranged as to give 90 amperes at 250 volts when running at a speed of 800 revolutions per minute. From 60 to 70 amperes are utilised in the alternator, the remainder being available for lighting (which is done from accumulators) and general experimental purposes.

This short sketch will, I trust, give some idea of the magnitude of the plant which is now in full working order and which has all been erected, at a very considerable cost, for the express purpose of proving the Reahman-Parker system of commercially producing phosphorus by the new application of electricity to this manufacture.

The process is carried out in the following way:—

The raw materials all carefully and intimately mixed together are introduced into the furnace in the condition shown by the specimens on the table, the current is then turned on and shortly after indications of phosphorus make their appearance.

The gases from the furnace pass away to large copper condensers—the first of which contains hot and the others cold water—and finally they pass on to the air.

As the phosphorus is distilled off from the mixture the residue in the furnace forms a liquid slag, which from time to time is tapped out at the bottom of the furnace, fresh phosphorus-yielding material being introduced at the top. In this way the operation is a continuous one, and we have every reason to believe it can be continued for days without intermission.

Slag Furnaces.—I have here specimens of the slag which has been tapped from the electric furnace in the manner just described. The charge as introduced into the furnace can be made to contain as much as 15 per cent. of elementary phosphorus, and as the weight of the slag from this is rather less than half the weight of the former, and that, moreover, it contains on an average only about one per cent. of phosphorus, it will be apparent that the decomposition is remarkably perfect.

The charges for the furnaces are made up with raw materials, e.g., native phosphates, without any previous

chemical treatment, and that the only manufactured material—if it may be called such—is the carbon to effect the reduction.

The crude phosphorus obtained in the condensers is tolerably pure, as may be seen by the specimen before you, and is readily refined in the usual way.

It may be well to mention that we do not now put the entire current from the dynamo through one furnace. We find that the advantage is on the side of a series of furnaces yielding about one hundredweight and a half of phosphorus each per day.

It was intended to have exhibited photographs of the engines and boilers and also of the dynamo and set of furnaces for to-night's meeting, but unfortunately this has not been accomplished in time.

DISCUSSION.

The CHAIRMAN thanked Dr. Readman for the series of interesting and valuable papers on this important subject which he had read to the Section. He felt bound to say that in his opinion Dr. Readman had hardly done himself justice in this last paper, so far as regards reference to his own labours. From personal knowledge he could say that Dr. Readman had for some years devoted an enormous expenditure of labour, time, and money to the perfection of the process he had described. He had had many obstacles to overcome, and he hoped that his ingenuity and application would receive the reward so well deserved. There were one or two points on which he should like some further information. In the first place he would ask whether basic slag had been tried as a source of phosphorus. He should also like to know how the carbons used in the furnace were manufactured, and how they stood the very high temperature of the furnace. The phosphide of iron which Dr. Readman had exhibited was in his opinion a very interesting substance, and it would be interesting to have a somewhat fuller description of its properties. He understood that it was absolutely necessary to the success of a continuous process that a fluid slag must be produced, to be easily run off. Great difficulty had been experienced in getting any lining that would stand the great heat and action of the flux. He knew Dr. Readman had employed, amongst other things, a water jacket, and his experience in this direction would be interesting to the Section. There must also be some difficulty experienced in condensing such a volatile body as phosphorus, especially when the temperature at which it was produced was taken into consideration. The "crude" phosphorus obtained was, he thought, very pure in comparison with specimens of crude phosphorus he had seen obtained by other processes.

Mr. G. BELBY had failed to gather from the paper how Dr. Readman had got over the difficulty experienced with Cowles' furnace, namely, the concentration of the heat in a small area and consequent expulsion of oxygen from the raw material and reduction of the bases to the metallic state. He would be glad to have some further details about the construction of the furnaces now used.

Dr. J. R. PATERSON asked whether in the blast furnace experiments the injection of steam had been tried, and if so, what was the result?

Dr. G. G. HENDERSON asked if the charge of raw material was prepared in the way described in the second part of Dr. Readman's paper, and if the quantity of phosphorus lost in the form of phosphide of iron or otherwise in the slag was at all considerable?

Dr. J. B. READMAN, in reply, said that basic slag was the first substance tried, but that it had been found of no avail, because under the conditions of the manufacture any iron in the raw material combined with phosphorus, forming a phosphide containing 23—24 per cent. of phosphorus, and there was sufficient iron in many of the basic slags to take up nearly all the phosphorus in this way. With regard to the carbons, those used by the Cowles Company are manufactured in America, and cost 8s. to 10s. each. In place of these they had substituted a simple arrangement, using gas carbons. The phosphide of iron obtained in the manufacture, as stated above,

contains 23—24 per cent. of phosphorus, corresponding pretty closely to the formula Fe_2P_3 . It is steel-grey in colour, hard and extremely brittle, and breaks with a crystalline fracture. It is very fusible and extremely insoluble in hydrochloric and nitric acids, though sulphuric acid attacks it slowly. The difficulty attending the concentration of the heat between the carbons was overcome by reducing the size of the furnaces. Their furnaces were, generally speaking, similar in construction to the Cowles' furnace, but they used a series of small furnaces, capable of turning out about $1\frac{1}{2}$ cwt. of phosphorus per day, instead of large ones. It was found that the brickwork did not suffer, the heat being concentrated between the poles. The operation of tapping is very simple, being carried out in the same way as the tapping of a blast furnace. The slag is quite liquid enough to flow out readily under the pressure of the superincumbent charge. The fusion of the charge is a sign that the phosphorus is expelled from it. In the blast furnace experiments the action of moisture was found to result in the formation of phosphoretted hydrogen. The charge was prepared in the manner described in the former paper. With regard to loss of phosphorus in the form of phosphide of iron he would quote the results of a working experiment:—127 parts of the mixture were used, containing 13 per cent. of phosphorus, 14·3 parts of phosphorus were volatilised, and 2·3 parts of phosphorus were lost, chiefly in the form of phosphide of iron. It would thus be seen that about 86 per cent. of the phosphorus passed on to the condensers. All the iron in the raw material was obtained as phosphide after the treatment in the furnace, and was run out with the slag.

METHYLATED SPIRITS.

BY D. R. DOTT, F.C.S., F.I.C.

THE disadvantages attending the use of methylated spirit as compared with pure alcohol are known to every chemist, but are more particularly impressed on one who is engaged in pharmaceutical manufactures. Whether the methylated spirit is employed simply as a solvent, as in the crystallisation of an alkaloid, or is converted into new products as in the preparation of ether or chloroform, there are drawbacks attending its use. It is frequently necessary to use methylated spirit or alcohol not only in the separation of alkaloids and active principles, but also in the purification of organic and mineral salts. For instance, a salt may be so extremely soluble in water that it is hopeless to employ that menstruum for its crystallisation, in which case spirit is generally suitable. In all these instances methylated spirit is objectionable, because of the persistent odour which remains after evaporation of the spirit, and sometimes also on account of the colour imparted to the salt. The enduring empyreumatic odour left by methylated spirit is often a fatal objection to its use. What is evidently required, is a methylated spirit or its equivalent which shall leave no residue when evaporated. By an Act recently passed (53 Vict. c. 8), the Commissioners of Inland Revenue have power not only to use some substance other than wood naphtha for methylating, but may also use any mixture or combination of substances for that purpose. It is not expressly stated, but is presumably implied, that the mixture must not be less than one-ninth of the volume of the alcohol to which it is added. In a paper formerly contributed to the proceedings of this Society,* the use of highly purified wood spirit or methyl alcohol was advocated as the methylating material, the methylated spirit so prepared to be used only by manufacturers. From a manufacturer's point of view such a spirit would probably be most satisfactory, but regarded from an excise aspect there are some weighty objections. These are, that so pure a spirit is scarcely distinguishable from alcohol by ordinary physical and physiological properties, but requires the application of delicate chemical tests. Since the paper above referred to was written, I have had considerable additional

* Vol. VI., 805.

the water on rising being driven out through the perforations, which are covered on the inside with filtering substances, such as asbestos, charcoal, &c. Air-pipes carry the air through the bottom plate of the inner cylinder, and are bent out at their lower ends to come into contact with the inside of the revolving drum, being shaped so as to cut away the deposited material, which then passes out through holes in the bottom of the drum. There are seven claims and three sheets of drawings.—B.

Improvements in Apparatus for making Infusions. C. J. Jones, London. Eng. Pat. 3661, March 7, 1890. 8d.

THE object of the invention is to facilitate the discharge of the infusion through the filter surface.

A cylinder, capable of being reversed, and containing a piston, has both its ends closed by removable covers, which are kept in position by arms fixed on one side of the cylinder, and carrying a screw. These arms are made in one piece, with a hollow axis, which extends from the centre of the side of the cylinder, and is fitted over the end of a pipe from the boiler. Across each cover internally is a perforated filter plate, and it is also provided with a draw-off tap. The substance to be infused being placed upon the filter surface, and the cover being fixed, the cylinder is reversed, thus bringing the filter plate and material to the top. Boiling water under pressure is then admitted to the cylinder between the cover and the piston, and when the draw-off tap on the cover, which is now at the bottom, is opened, the piston is forced downwards, and the infusion is forced out through the opened tap.

The cylinder may be made with a removable cover at one end only, in which case the cylinder is fixed, and the removable cover is at the bottom.—E. S.

Improvements in Condensing Apparatus for Steam and other Vapours. J. Schwager, Berlin, Germany. Eng. Pat. 3915, March 12, 1890. 8d.

IN this apparatus the currents of vapour and the condensing liquid are made to flow in contrary directions, the air and water pumps being made to exhaust both the liquid of condensation, the condensing liquid, and the uncondensed vapour or air.

A closed upright vessel or condenser has within it a number of central helically-arranged plates, perforated or unperforated, forming a winding staircase. The condensing liquid is caused to flow down from step to step to the bottom, where a suitable liquid seal or trap is formed communicating at the outer end with an air and liquid pump, which at the same time is made to communicate by a pipe with the top of the condensing chamber, and the steam or vapour to be condensed is made to enter through a pipe at the bottom. The steam being prevented by the seal from passing down directly into the pump, rises in the helical passage between the plates in the contrary direction to, and through the descending condensing liquid, to the top of the chamber, and becoming condensed the liquid of condensation flows down together with the condensing liquid, while the uncondensed vapour is drawn off by the pump. Several modifications of the apparatus are shown in the drawing attached to the specification.—E. S.

Improvements in Continuous Mechanical Filters for Chemical or other Purposes. H. Yeomans, Northwich. Eng. Pat. 4005, March 14, 1890. 6d.

A CYLINDER of filtering medium, as flannel, wire gauze, &c., is placed, preferably, with its axis vertical, and has a central hollow shaft carrying a helix, which fits the interior of the cylinder closely. The shaft is rotated by suitable gearing, and is supplied through a pipe with water or other liquid, which enters the cylinder through perforations in the upper part of the enclosed shaft. The cylinder is eased in a larger one of iron, or other material, and the two are securely joined at the bottom. A pipe entering the bottom of the internal cylinder supplies the material to be filtered, and

another pipe from the bottom of the external cylinder carries away the filtered liquid. The shaft being rotated, the liquid and gases rapidly percolate through the inner to the outer cylinder, the solid particles being raised by the screw past the perforations in the shaft, whilst the liquid runs down again. Water entering through the perforations still further washes the original liquid from the salt or other solid material, which is gradually pressed upwards, becoming further dried in its course. It is then discharged through a pipe into a worm, from which it is carried to a drying chamber or other desired position.—E. S.

Improvements in Apparatus for Evaporating Salt Water for Supplying Extra Feed for Marine Boilers. J. Kerr, Liverpool. Eng. Pat. 5891, April 18, 1890. 8d.

THE patentee uses an upright, closed, cylindrical, jacketed vessel, the jacket of which is in open communication with the surface condenser of a steam engine. The uncondensed steam from the condenser evaporates the water contained in the vessel, from which the resulting vapour is led back to the condenser. A small steam coil in the lowest part of the vessel can be supplied with steam from the boiler to aid the operation if required. The drawings show one arrangement and there are six claims.—B.

Improvements in Fluid-tight Joints or Couplings for Pipes, and the like. J. Newton, London, and D. A. Quiggin, Liverpool. Eng. Pat. 5992, April 21, 1890. 8d.

THIS invention relates to joints connecting two pipes, or a pipe and vessel, so that their interiors are in fluid-tight communication, and is expressly applicable to joints between the tubular heating surfaces and the pipes or diaphragms in evaporators, &c. such as described in Eng. Pat. 533 of 1889 (this Journal, 1890, 43 and 481).

This is done by interposing between the surfaces, which would otherwise abut in making the joint, a ring or washer of tin or some suitable material, which is secured to one surface by being cast in a circular groove of a dove-tail cross section. The abutting surfaces may be smooth, but preferably each has on its face one or more concentric V-grooves so disposed as to accurately interlock. This strengthens the joints and prevents the spreading of the softer surface by undue pressure. There are six claims.—E. S.

Improvements in Evaporating Pans. G. Fletcher, Litchurch. Eng. Pat. 6484, April 28, 1890. 8d.

THIS invention relates to pans for evaporating cane juice or other liquids, whether in open pans or in closed vessels in a vacuum more or less complete, and is intended to promote the circulation of the boiling liquids. The evaporating pan has its heating surface preferably formed by tubes either fixed in tube plates secured to the sides of the pan, or contained in a drum also secured to the sides, both arrangements being also fitted with one or more circulating tubes, whose areas equal the combined areas of the heating tubes. The requisite quantity of liquid being placed in the pan, steam is admitted to the space between the tube plates, and round the circulating tube, or to the interior of the drum, and the circulation of the liquid is promoted. The construction of the tube plates and drum are shown on the four sheets of drawings accompanying the specification.—E. S.

Improvements in Filtering Apparatus. B. Hunt and W. M. Mackey, Leeds. Eng. Pat. 7075, May 7, 1890. 8d.

THIS invention is designed for rapid filtering when dealing with large quantities of liquids containing suspended matter, as sewage, &c., and is intended to bring the solid or semi-solid matter into a condition for being removed. To save expense in the frequent renewal of sand or filtering material, a sand carrier is used in the form of a grating, of diamond or

through the check valve *h* which prevents the return of gas. The freezing coil *E* communicates with the bottom of *C* through the pipe *i* and valve *i*, which latter is moved automatically to open and close the communication as required. The other end of the freezing coil *E* is jointed through *F* to the top of, and reaches down into the vessel *A*, and is also fitted with a back-pressure valve *K* to prevent gas returning into it. The operations are carried on as follows, viz.: *A* and *B* having been charged with liquid ammonia as indicated, the vessel *A* is heated, which may be done by means of gas as at *g*. The vapours rise into *B*, any moisture carried over being returned through the trapped pipe *d*, whilst the gas passes on and is liquefied under pressure in the coil *b*, and cylinder *C*. When the vessel *A* has been nearly depleted the flame is automatically removed or extinguished, and the vessel cooled. At the same time the valve *i* at the bottom of *C* is gradually opened and the liquefied ammonia allowed to escape into the coil *E*, where it evaporates and causes great reduction of temperature, whilst itself returning through the pipe *F* to the cylinder *A*, and being absorbed by the liquid therein ready for re-evaporation. For the purposes of the automatic regulation the small cylinder *f* passes through the top of the vessel *A*, and is closed at the bottom. It contains oil which expands by heat and thereby moves the piston *f*₁ fitted on top, and which, by means of the levers and rods shown, serves to regulate the supply of gas through the pipes *G*, and that of the cooling water through pipes *Q*, at the same time actuating the release valve *i* at the proper intervals. The parts marked *m*, *n*, *t*, and others are provided for aiding in starting the apparatus.—B.

Improved Apparatus for the Vaporisation of Liquids. H. J. Allison, London. From "The National Salt and Chemical Company," New York, U.S.A. Eng. Pat. 19,835, December 5, 1890. 8d.

The apparatus is designed for the evaporation of saline, saccharine and other liquids, and consists principally of a high vessel or tower, in which a current of heated air or gas is forced upwards coming in intimate contact with the liquid which descends in finely subdivided showers, whereby the moisture is absorbed by the gases and the liquid is concentrated. The drawings show three different arrangements and there are four claims.—B.

An Improved Process of and Apparatus for Distilling and Refining Petroleum and other Hydrocarbons, applicable also for Distilling and Refining Animal, Vegetable, and Fruit Oils, Saccharine Juices, Syrups, Essential Oils, and other Substances. H. E. Ryecroft, New York, and A. Mason, Brooklyn, U.S.A. Eng. Pat. 249, January 6, 1891. 8d.

See under III., page 456.

An Improved Filter for Oil and other Liquids. C. A. Koellner, Neumühlen, Germany. Eng. Pat. 474, January 10, 1891. 6d.

See under XII., page 472.

An Improved Process for Centrifugally Treating Particles of Metallic or Mineral-bearing Substances of Different Degrees of Specific Gravity. O. B. Peck, Chicago, U.S.A. Eng. Pat. 652, January 13, 1891. 8d.

THE patentee proposes to separate mineral particles of different degrees of specific gravity, when in the condition of powder or small granules, by subjecting them to the action of gradually decreasing centrifugal force in a revolving vessel. He finds that the heavier particles are more

difficult to discharge and require higher speed than the lighter ones, and he avails himself of that fact for their separation by commencing his operations when the rotating vessel has attained the highest speed and gradually reducing that speed as he proceeds. The drawings show some devices by means of which the desired gradual change in speed is brought about.—B.

Improvements in Machinery for Centrifugally Treating Particles of Metallic or Mineral-bearing Substances of Different Degrees of Specific Gravity. O. B. Peck, Chicago, U.S.A. Eng. Pat. 674, January 13, 1891. 6d.

IN centrifugal machines for treating the separation of mineral particles of different degrees of specific gravity by means of the action of centrifugal force, the patentee introduces a flexible diaphragm or cup-shaped partition, with a view to retaining the finer particles a sufficient length of time under the influence of the treatment. These particles, more particularly when water is introduced, have a tendency to fly off too soon, hence the necessity for such a device which is indicated in the accompanying illustration.

DETAILS OF CENTRIFUGAL APPARATUS.

A is the revolving vessel strengthened on its circumference with layers of tightly-wound wires, *B* the shaft held in the bearing and stationary bracket overhead. From the bracket is suspended a casing with internal projecting discs or pins *C*, and the shaft carries a corresponding bush *D*, with enlarged flange at its lower end, to which the ring *E* is secured as well as the inner edge of the canvas diaphragm or cup *F*, which approaches the revolving vessel at the upper edge and rotates with it. The materials are fed through the holes shown in the overhead bracket, and find their way between the casing and bush to the bottom of the vessel underneath the canvas. As the vessel fills, the canvas is gradually pushed in, and the finer particles creep along on its under surface until they are finally discharged at the top, leaving the heavier parts within.—B.

II.—FUEL, GAS, AND LIGHT.

PATENTS.

Illuminating by Means of the Incandescence of Refractory Substances. W. H. Spencer, London. From O. Fahnchjelm, Stockholm, Sweden. Eng. Pat. 5646, December 5, 1883. (Third Edition.) *Sd.*

For the purposes of illumination, suitable refractory substances, such as the oxides of magnesium, calcium, zirconium, silicon, or similar oxides are (either singly or mixed) made into the form of small wires, pins, or lamellae. These wires are then fixed in holders and arranged so as to be heated to incandescence by means of the combustion of water-gas. In manufacturing the wires the finely powdered oxide is mixed with a solution of starch or gum, made into a plastic mass and pressed through a small hole or die so as to obtain a thread of suitable thickness. The thread is cut while soft into the requisite length, dried and then burned at a high temperature. This last is essential, or the pins are liable to twist and bend by the heat of the water-gas flame.

A number of wires made in the above way are fixed in rows or rings in a socket in such a way as to obtain the full effect of the heat; such an arrangement is termed a comb. The socket is of iron or brass, of U shaped section, and is filled with a plastic mass of damp clay or magnesia, in which the wires are fixed by inserting one end and afterwards drying.

Ordinary gas burners are available, but the fish-tail form is preferable. (See this Journal, 1886, 424; 1889, 533 and 534.)—D. A. S.

Improvements in the Manufacture of Illuminating Gas and Apparatus for that Purpose. R. Mannesmann, Landore. Eng. Pat. 1237, January 23, 1890. *Sd.*

THE object of this invention is the production of illuminating gas from carbonaceous material without the aid of external heat. The process is carried out in a vertical retort or producer, which is provided with a suitable valve at the top for feeding it from time to time, and an ash-pit at the bottom; situated at about the middle of the producer there is a passage leading to a chimney, and near the top of the producer there is an outlet for gas and a passage communicating between the gas outlet and the bottom of the retort, this passage being provided with a fan or blower; all the openings and passages are fitted with suitable valves. The retort having been charged with coal and ignited below, air is admitted periodically and the chimney flue opened so that the lower part of the charge soon becomes incandescent; the air supply is then shut off and the chimney flue closed, the gas outlet and the channel communicating between the upper and lower parts of the producer being opened. A portion of the gas produced is then caused to circulate through the communicating channel, in the direction from the top to the bottom of the producer, by means of a steam injector, so that it is forced through the incandescent coke; in passing upwards it heats the upper and cold parts of the charge and a further quantity of gas is produced. A portion of this gas is led off into the gas main, the rest being employed as before for transmitting heat from the lower to the upper portions of the charge. When the incandescent coke is partially cooled the gas outlet and communicating channel are closed, air is again admitted into the ash-pit, the chimney flue opened, and the whole process repeated as described above. Two retorts are worked in combination with the same gas main and chimney flue, so that when air is being admitted into one the other is passing gas into the main, and *vice versa*.

—F. S. K.

Improvements in the Production of Water and Illuminating Gas, and Apparatus for that Purpose. R. Mannesmann, Landore. Eng. Pat. 1238, January 23, 1890. *Sd.*

THE water-gas is produced by decomposing steam by causing it to pass repeatedly through incandescent fuel; illuminating-gas is made in a similar manner, the steam

being passed through heated coal. The apparatus employed consists of a producer filled with fuel, and two regenerators provided with suitable valves so that they may be made to communicate alternately with the producer. The producer having been ignited, and one of the regenerators raised to a high temperature (the other being heated in the meanwhile by the combustion of a portion of the gas), a circulation of the gas is set up from the top to the bottom of the producer through the heated generator by means of a steam injector; the gaseous mixture, thus strongly heated, passes into the lower part of the producer, where it gives up some of the heat taken up in the regenerator, and, on the other hand, takes up heat from the producer by the decomposition of some of the steam carried with it. In this way some of the water-gas is employed for transferring heat from the regenerator to the fuel, some is drawn off, and some utilised for heating the other regenerator, so that when the one in use has cooled down the other is ready to work, and by reversing their connexion with the producer the process can be continued.—F. S. K.

Improvements in the Production of Coke, and Apparatus for that Purpose. O. Imray, London. From R. Mannesmann and M. Mannesmann, Bliedinghausen, Germany. Eng. Pat. 1283, January 24, 1890. *Sd.*

THIS invention is intended to produce a better variety of coke, and to utilise the gas and heavy hydrocarbons. A regenerator is used, and the gases from the top of the oven are led down through one of the regenerators and back into the bottom of the oven, a portion of the gas being used to heat the regenerator. A steam or other injector is used. In this way the distillation of the coal is effected by the repeated passage of a part of the gaseous product, external heating is rendered superfluous, the products are increased, and the cost diminished. The excess of gas produced beyond that required for heating the regenerators can be used for other purposes. If a second circulating apparatus is applied, which sucks the hot distillation products through fresh coal, the decomposing tar binds the particles of coke together, and a firmer coke can thus be produced than in the ordinary way.—D. A. S.

Improvement in Gas Producers. O. Imray, London. From R. Mannesmann and M. Mannesmann, Bliedinghausen, Germany. Eng. Pat. 1285, January 24, 1890. *6d.*

IN order to prevent the product of an ordinary gas producer containing a mixture of tar and other heavy hydrocarbons which would be precipitated in the passages, and so interfere with the draught and render the gas more impure, the gases from the top are led or drawn down and introduced again into the bottom of the producer. By this arrangement the tar, &c. is converted into permanent gas, and any carbon dioxide is reduced to carbon monoxide. The gases are led, by means of a pipe, from the top, outside, and down to the bottom of the producer, a steam or air injector or other appliance being used to effect the circulation of the combustion gases down from the top and up through the fresh coal.—D. A. S.

Improvements relating to the Production of Water-Gas and Generator-Gas, and to Apparatus connected therewith. J. von Langer and L. Cooper, Leeds. Eng. Pat. 4223, March 18, 1890. *Sd.*

THE object of this invention is to procure an abundant supply and a good distribution of air for combustion, and a rapid discharge of the gaseous products of combustion so as to increase the proportion of carbon dioxide during the first stage of the process, and in this way obtain an increased quantity of water-gas from a given quantity of fuel. Various kinds of furnaces are shown in the drawings accompanying the specification; they are so constructed that air can be admitted by suction through a large number of inlets distributed over the circumference and height of

the furnace (see Eng. Pat. 7252 of 1889; this Journal, 1890, 170), and in some cases also through apertures in an air-chamber built into the top or bottom of the furnace. The products of combustion are discharged through a stack in which a steam, compressed air or gas injector is placed to produce the necessary suction. Steam jets for the production of water-gas are situated in the valved air-openings.

—F. S. K.

Improvements in Inclined Gas Retorts, and in Apparatus for charging the same. C. Hunt, Birmingham. Eng. Pat. 5078, April 1, 1890. 8d.

INCLINED retorts as at present used have a tendency to slide upon their bearings. This disadvantage is got over by moulding snugs, suitably shaped and placed, on the upper and lower surfaces of the retort; those on the under side of the retort take a vertical bearing upon the walls supporting them, thus converting a side thrust or strain into a vertical one, whilst upon the upper snugs the cross walls may be built and supported.

The apparatus for charging the retorts consists essentially of a small hopper, provided with a suitable shoot, and movable vertically on an iron framework mounted on wheels; the movable hopper is supplied with coal from a trough or continuous hopper furnished at convenient intervals with shoots, and running through the retort-house. With this charging apparatus the curved mouth-piece usually attached to inclined retorts may be dispensed with.

—F. S. K.

Improvements in Apparatus for producing Combustible Gas for Gas-Motor Engines or other purposes. S. Griffin, Bath. Eng. Pat. 6217, April 23, 1890. 8d.

WITHIN, and at the bottom end of, an upright cylinder closed at both ends, is placed a vessel rather smaller in diameter and about half the length of the cylinder; the annular space between the two is filled with water, which forms a joint or luting for a bell or receiver, moveable vertically, in which the gas is stored; the smaller vessel is constantly charged with liquid hydrocarbon, the supply being regulated by a valve and float arrangement. Air, heated by a small coil to compensate for the loss of heat by evaporation, is forced through the liquid hydrocarbon in such a manner as to ensure perfect saturation, the supply pipe being so arranged that the liquid cannot flow back when no air is passing. When the receiver becomes filled with gas the air-supply is shut off automatically by means of a suitable valve.—F. S. K.

Improvements in the Manufacture of Gas, and Apparatus therefor. J. H. W. Stringfellow, London. Eng. Pat. 6575, April 29, 1890. 8d.

A NON-LUMINOUS gas of great heating power, and which may be manufactured on a large scale, is produced by causing atmospheric air at the ordinary temperature to pass first through absorbent porous material saturated with liquid hydrocarbon, and then through similar material saturated with water at the ordinary temperature. The porous material is dome-shaped and is enclosed in a chamber, the floor of which is covered with a layer of hydrocarbon or of water, so that the material is kept constantly saturated by means of capillary attraction. The gas obtained in this manner can be employed for incandescence lighting, or it may be converted into a luminous gas by further charging it with hydrocarbon vapour. A portable lamp for use with this kind of gas is also described.

—F. S. K.

Improvements in Incandescent Lighting by means of Calcfacient Gases, and in Apparatus therefor. G. Macaulay-Cruikshank, Glasgow. From J. C. Reissig, P. F. Maccallum, La Plata, Argentine Republic, and J. L. Regeriösgatan, Stockholm, Sweden. Eng. Pat. 7335, May 12, 1890. 8d.

THIS is an improvement of the Fahnshjelm system (see page 452). The combs and burners are inclined to any required angle to obtain a better downward and more equal illumination. Further, to secure effectual contact of the flame with the comb, a flame of any suitable refractory material (metallic or otherwise), preferably with a reflecting surface, is placed immediately behind the combs in such a way as to guide the flame in the direction of the axes of the wires forming the comb, and to prevent the flame leaving the comb through the action of upward currents of air. These guide reflecting surfaces should be placed no farther than one inch from the combs but not so near as to come into contact with the flames. In practice excellent results have been obtained with a space of three-eighths of an inch between the combs and the guide reflecting surfaces; special supports can be dispensed with, and the combs fixed direct to the guide reflecting surface.

To effect economy, and obtain still better light, the principal of regeneration may be applied by using the heat of the products of combustion for heating the air required for combustion.

For details of these various modifications the drawings attached to the specification must be referred to.—D. A. S.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

The Colouring Matter of Red Carbohic Acid. E. Fabini. Pharm. Post. 1891, 24, 2, 25, 41, and 105; Chem. Zeit. Rep. 15, 25 and 45.

A SERIES of investigations on the cause of the reddening of carbohic acid have shown it to result from the action of hydrogen peroxide on carbohic acid containing metallic salts in presence of ammonia. Pure carbohic acid is not coloured by hydrogen peroxide, either alone or in presence of ammonia; nor is there any colouration in presence of metallic salts and hydrogen peroxide when the sample is quite free from ammonia. But carbohic acid containing metallic salts is coloured by hydrogen peroxide in presence of traces of ammonia with the formation of the red colouring matter, and the salts of iron or of copper in the proportion of 1:180,000 or even 1:300,000 of phenol produce a distinct colouration. The formation of the colour is, according to the author, due to the ammonia being first absorbed by the phenol with the formation of ammonium phenate, which latter is then transformed into a phenate of the metal present (iron or copper), and this is converted into the red colouring matter by the hydrogen peroxide, the free metal being simultaneously separated. Copper sulphate precipitates green copper phenate from ammonium phenate, and this treated with hydrogen peroxide yields the red colouring matter, hydrogen being evolved at the same time.

The red colouration takes place immediately on warming carbohic acid containing the necessary ingredients for its formation; this accounts for the sudden turning red of many samples of carbohic acid on warming. Carbohic acid, free from metallic salts, can be warmed with ammonia and hydrogen peroxide without any formation of the red colour.

Phenerythrene is the name proposed for this colouring matter, which is always contained in the liquid portion of the carbohic acid, i.e. where the ammonium phenate is. Phenol is very soluble in ammonium chloride solution, one drop of this reagent being sufficient to dissolve 1 grm. of phenol, when a considerable lowering of temperature takes place.

Phenylthrene dissolves in alcohol: when precipitated by water it forms light cinnamon-coloured flocks which can be purified by dissolving first in alcohol and then in ether after evaporating off the former solvent. The ethereal solution leaves a black brittle body behind, which is the red colouring matter. It colours carbolic acid red, the colouration being evident with one part of the colouring matter to 300,000 of phenol. The substance has neither taste nor smell: it is amorphous and volatilises on heating, forming a yellow vapour which condenses to a rose-red deposit on cooling. Sulphuric acid gives a blue colouration with the product, which is itself quite free from metal, as shown by ignition with nitre, when the residue is found to be quite free from any metal, although the presence of a metallic salt is necessary for its formation.

The phenylthrene can be readily produced by adding half a drop of ammonia and a drop of hydrogen peroxide to 10 cc. of liquid phenol placed in a test tube. On warming no colouration results if the sample be pure, but if a clean knife point be inserted into the warm mixture the colouration is at once produced.—C. A. K.

The Refining of Petroleum and Lubricating Oils, and the Apparatus used therefor. Schestopal. Chem. Zeit. **15**, 352—354.

PETROLEUM and lubricating oils obtained by the distillation of mineral oil are generally refined by treatment with sulphuric acid and caustic soda, followed by washing with water. Sulphuric acid at 66° B. is mostly employed, the amount used ranging from 2—4 per cent. for petroleum to 5—10 per cent. for lubricating oils. The acid is well agitated with the oil, either all at once or preferably in several instalments, the acid being allowed to settle thoroughly after each treatment. The acid combines with and dissolves the olefines and aromatic hydrocarbons contained in the oil, and an oxidising action also appears to take place, indicated by the evolution of sulphurous acid. This latter action increases with the specific gravity and temperature of the oil, so that it is well to keep the mixture cool. The time of treatment varies from 1—2 hours, the operation being finished when a sample of the oil shaken with caustic soda solution appears milky and white or only slightly yellow (petroleum), or, when the original green-brown colour has changed to violet-red (lubricating oil). The loss during acidification is 1—3 per cent. for petroleum, and 8—15 per cent. (seldom 20 per cent.) for lubricating oil. The oil is next washed with water and well agitated with a caustic soda solution at 30—33° B. The intermediate washing is best omitted in the case of lubricating oils, since it leads very often to the formation of emulsions which are separated from the oil with great difficulty. The treatment with soda is continued for 5—10 minutes at the ordinary temperature in the case of petroleum; whilst with lubricating oil the action is carried on at 40—50° C. until the violet colour of the oil is changed to a wine-yellow tint. The consumption of soda lye at 33° B. is about 1—1.5 per cent. Too long a treatment with soda must be carefully avoided in order to prevent the extensive oxidation of the oil and the consequent production of the sodium salts of organic acids. The salts are partially saponified during washing, the acid liberated being dissolved by the oil and leading to turbidity in the finished product. The oil after being separated as completely as possible from the lye is washed with cold water (for petroleum), or with water at 60—70° C. (for lubricating oil) until perfectly neutral. Thorough washing is of the greatest importance. Petroleum containing sodium salts in solution burns badly owing to the incrustation that soon forms on the wick; besides which sulphurous acid is given off, if sulphates, &c. be present. The water should be as free from dissolved salts as possible, especially for washing lubricating oils. After washing, petroleum is left in reservoirs for 12—36 hours so that the last traces of water may settle. Or, after standing for an hour it may be filtered through a mixture of wood-shavings and salt. In either case the oil will be ready for the market. Lubricating oil is kept in a vessel heated by steam until the bulk of the water has settled. It is then transferred to a shallow

double-bottomed pan and "boiled" by steam until it is quite bright and clear, and no longer froths. In many cases the oil is, after boiling, filtered through animal charcoal, &c.

The apparatus in which the oils are chemically treated may be divided into two groups: 1. Those in which some mechanical stirring apparatus is employed. 2. Those in which agitation is effected by a strong current of air entering the bottom of the apparatus. The author is strongly of opinion that those of the first class are much to be preferred. Agitation by means of air currents is certainly more thorough than by any mechanical device; but when the ready oxidizability of petroleum, and more particularly of lubricating oil, and the injurious influence of the acids so produced, are considered, it will be seen that mechanical stirring arrangements are really the more advantageous. In the case of air agitators there is also a much greater tendency towards emulsification, which is very objectionable. The turbidity appearing in finished petroleum, &c. is chiefly due to the presence of organic acids and salts, which gradually separate. The turbidity which badly refined oil sometimes develops in barrels is most likely caused by the action of organic acids on traces of chalk contained in the glue with which the interiors of the barrels are coated. (See also this Journal, 1891, 39.)

Petroleum Spirit in Germany. J. Schenkel. Chem. Ind. **13**, 512.

PETROLEUM spirit has been known in Germany for about 40 years, its first use being for cleaning purposes. At the present time the crude naphtha is refined into four distinct products:—1st, petroleum ether (boiling point 70°—120°, sp. gr. 0.640—0.650); 2nd, "benzine" (boiling point 70°—120°, sp. gr. 0.700); 3rd, "ligroin" (boiling point 120°—135°, sp. gr. 0.730), and 4th, cleaning oil (boiling point 130—160°, sp. gr. 0.745—0.750). The first of these is used for the production of air-gas; the second, for the extraction of oils and fat from seeds and bones, for miners' safety lamps, for the so-called "chemical washing," as a substitute for turpentine in paints and varnishes, and for washing down machinery and printers' plates. The "ligroin" is burnt in specially constructed lamps, and the last product is also used for cleaning machinery and to replace turpentine.

The price of the spirit has varied from 30 marks per 100 kilos, in 1869 to 42 in 1872; since which year it has fallen to from 18 to 20 in 1890. In the year 1880 a tax of 6 marks per 100 kilos, gross was imposed alike on the crude and in the refined product. At present the spirit used for cleaning bones, in rubber works, in "chemical washing," and in the palm oil trade, is untaxed. A drawback is also allowed on all exported spirit, for every 100 kilos, net, the tax is remitted on 125 kilos, gross of the dutiable crude product. The German railways also stipulate that all petroleum must be packed in casks, on which a special tax is imposed, on first importation the casks being taxed under a special schedule at a still higher rate, and if the petroleum is imported in bulk, the non-existent casks are still charged for.

The consumption of petroleum spirit has probably reached its maximum, and a fall in price may be expected.

—F. H. L.

Paraffin and Bitumen in Brown-coal Tar. E. von Boyen. Zeits. f. angew. Chem. 1891, 101—104.

ZALOZIECKI (this Journal, 1888, 349) has proposed a method of estimating the crystalline paraffin and the bitumen in a mixture of liquid and solid hydrocarbons by using amyl and ethyl alcohols. The author has adapted this process for the analysis of brown coal tar. Ten grms. of tar were placed in a small flask, dissolved in amyl alcohol (sp. gr. 0.837 at 17.5°), and the paraffin precipitated by the addition of hot almost absolute alcohol. No increase in yield was obtained by increasing the period of settling from one to five days, one day being sufficient. The temperature was 2 to 5°. The precipitate was brought

on to a tared filter and allowed to drain, then pressed strongly by means of a screw press into a small flexible eake. As the precipitate cannot be separated readily from the filter paper, the whole was cut in pieces, dried at a temperature of 120° for about 12 hours in a small porcelain crucible, and weighed till constant, the tare of the filter being afterwards deducted.

The proportion of amyl to ethyl alcohol was found to be of importance. For a tar poor in paraffin 4 parts of amyl alcohol and 8 parts of ethyl alcohol respectively should be taken to one part of tar; while for a richer tar, 4.5 to 12 parts respectively are required. If the percentage of paraffin be unknown, the highest results obtained by any mixture should be taken as the true yield.

The above method gives the total quantity of paraffin and bitumen. Although the precipitate largely consisted of lustrous scales in well-defined crystalline form, there were also present amorphous yellowish brown particles. Brown coal bitumen can be obtained in the purest form by extraction with amyl alcohol, and separating the yellow precipitate by recrystallisation. It occurred as a greyish-white amorphous powder melting at 90° to a shellac-like mass. It was evidently a resin acid and dissolved in potassium hydrate or carbonate-forming salts easily soluble in water, not crystalline, but which dried to a brownish-yellow mass. This resin acid can also be obtained by treating the brown coal with concentrated nitric acid or with potassium nitrate and dilute sulphuric acid as a crumbly wax-like mass. Nitric acid decomposes the woody and humus substance of the coal, while the resin acid resists oxidation. This resin is soluble in any of the brown coal oils, and also melts easily with the paraffin colouring it and setting to a homogeneous mass which is more brittle and not so crystalline as the pure paraffin. The melting point of the paraffin is also raised.

When the tar has cooled the paraffin and bitumen separate in more or less crystalline form and can be pressed free from oil. The paraffin as estimated in the products of distillation of the tar is always less than the results obtained by precipitation, as bitumen is decomposed on distillation. If the difference of the results got by distillation and precipitation be calculated as 80:100, the product is the quantity of bitumen in the tar which, subtracted from the results got by precipitation, gives the original quantity of paraffin in the tar, e.g., 10 grms. of a sample of tar treated with 40 grms. of amyl alcohol and 80 grms. of ethyl alcohol gave 25.4 per cent. of total solid hydrocarbons and 17.5 per cent. of crude paraffin by distillation, the difference being 7.9 per cent. This, divided by 0.8, showed 9.9 per cent. of bitumen, which, subtracted from the total solids, gave 15.5 per cent. as paraffin in the tar.

The author intends to follow up the subject in a future paper.—D. A. S.

PATENTS.

Improvements in the Process of Preparing Benzol and its Homologues, Naphthalene, and Anthracene from Petroleum, Petroleum Scales, Tar, Tar Oils, Paraffin, Vaseline, Ozokerite, and the like, and from Natural Illuminating Gas. F. Hlawaty and E. Friedmann, Vienna, Austria. Eng. Pat. 2242, February 11, 1890. 8d.

This specification relates to a pyrogenetic process for the preparation of aromatic hydrocarbons from fatty hydrocarbons. The apparatus consists of a boiler, heated by a furnace, to the top portion of which a retort, provided with a pressure gauge, is attached. The retort is connected with a condenser by means of pipes. Any one or mixture of the above-mentioned liquid or solid hydrocarbons is placed in the boiler and distilled at an internal pressure of 0.25–1 atmosphere. The vapours are led through the pipes in which the less volatile products condense, a portion of the liquid being returned to the retort, whilst another portion is made to pass through branch pipes, heated to redness, by which means it is again vaporised, converted into more volatile products, and condensed together with the vapours passing directly into the condenser. The distillate consists chiefly of benzene, toluene, xylene and cumene. The

process may be worked continuously, except that it is necessary to withdraw the coke from time to time from the retort. The non-condensed gases are led through red hot pipes filled with pieces of coke or pumice. Ordinary illuminating gas may be treated in a similar manner. After separating the benzene and other aromatic products in the usual way, the residual liquid is placed in a retort together with 10–20 per cent. of pulverised cellulose, in the form of moss, sawdust, dry rotten wood, &c., and some caustic alkali. The retort is then heated in a furnace, and a current of superheated steam at 750° F., or better of the vapours of acetic acid or methyl or ethyl alcohol, passed through. The escaping vapours are then led through pipes filled with pieces of coke heated to redness, and connected with a condenser. The solid hydrocarbons—naphthalene and anthracene—separate from the condensed liquid on cooling.

An Improved Process and Apparatus for the Continuous Distillation of Tar. H. Propfe, Mannheim, Germany. Eng. Pat. 2955, February 24, 1890. 8d.

The author proposes to convey the tar, as it deposits in the hydraulic main at a temperature of 70° C., continuously to the distilling apparatus; this obviates the loss of time and the danger of fire, consequent on stopping the distillation for recharging, or removing the pitch.

The apparatus consists of a multiple still, in the form of an elongated iron box, divided by partitions S reaching

APPARATUS FOR THE CONTINUOUS DISTILLATION OF TAR.

almost to the bottom, into eight separate compartments A¹ to A⁸, which thus communicate below the partitions, and are each provided with a still head H¹ to H⁸. The furnace is situated beneath the last compartment A⁸, and the gases from it are conveyed through flues in the direction of the arrows. The apparatus which is filled to two-thirds at starting is fed at T, the pipe S, terminating in a swan neck P, to maintain the constant level of the tar, being for the exit of the pitch. The distillation commences in the compartment A¹ and proceeds successively in the others. When the contents of A¹ are converted into pitch, which is indicated by the nature of the distillate, the tar is supplied continuously at T, and passes from A¹ below the first partition S until it reaches A⁸, gradually increasing in temperature as it does so. The distillates obtained from successive compartments have thus progressively higher boiling points, and the inflow of the tar and the heating are so regulated that first-runings and water are obtained from A¹ to A⁴, light oil from A⁵ to A⁶, and green oil, whose distillation is assisted by passing in superheated steam, from A⁷ to A⁸. The pitch passes out through the outlet tube, giving up its heat during its passage, and is of such a temperature that it will not ignite; if however it is too hard to flow, tar oil, deprived of its valuable constituents, is introduced into A⁸ by a pipe.

The apparatus may also have the form of a boiler with one or two flues, and it may be arranged for distilling under diminished pressure, and heated by superheated steam, circulating through pipes. For the purpose of insuring uniform heating when direct heat is employed, it is advantageous to use a regenerator, or gases from gas-retort furnaces.—A. R. L.

Improvements in the Distillation of Oils and other Viscous Liquids. J. Dewar, Cambridge, and B. Redwood, Finchley. Eng. Pat. 5971, April 19, 1890. 4d.

THE object of this invention is to provide against the danger attending the sudden evolution of steam or vapour in the still, and to render the boiling of the liquid tranquil

and uniform. Instead of feeding the liquid directly into the still, it is fed into a compartment of the still head, and allowed to trickle over an extended surface of conducting material, such as copper turnings, being there exposed to the vapours passing from the still. The more volatile portions of the feed are thus carried away in vapour, leaving only the less volatile portions to enter the body of the still.

—A. R. L.

Improvements in the Distillation of Hydrocarbon and other Oils. C. M. Pielsticker, London. Eng. Pat. 6466, April 28, 1890. 8d.

THIS patent claims certain improvements on Eng. Pat. 1706, 1882, whereby the difficulties of so regulating the temperature that the oil is immediately vaporised on entering the retort, and of avoiding the superheating of the same, and the consequent production of permanent gas, are removed. The distillation is conducted in a continuous manner, and the distillate is of uniform and lower gravity than that of the raw material. The oil, contained in a tank, is heated by a steam coil, and is forced by a pump or steam injector into an iron coil, contained in a cylinder filled with metal or salt of known melting point, or better, embedded in loosely fitting channels made in a block of iron, heating being accomplished in both cases by a furnace. In the second case the coil is formed of separate lengths of pipe, which can thus be readily cleared of carbon, and are connected and made continuous by covers at each extremity, provided with channels. By passing the oil rapidly through the coil the deposition of carbon is minimised, but this is better attained by gradually tapering the coil towards the end which leads to the retort. The latter is heated in a furnace, and is connected with a condenser. When it is intended to produce very light oils or permanent gas, the distillation is conducted slower and at a higher temperature, or it is retarded by baffle plates fitted in the retort, and by a valve placed on the goose neck connecting the latter with the condenser. —A. R. L.

An Improved Process of and Apparatus for Distilling and Refining Petroleum and other Hydrocarbons, applicable also for Distilling and Refining Animal, Vegetable, and Fruit Oils, Saccharine Juices, Syrups, Essential Oils, and other Substances. H. E. Ryeroff, New York, and A. Mason, Brooklyn, U.S.A. Eng. Pat. 249, January 6, 1891. 8d.

THIS invention is practically an extension of Grant and Mason's distillation process, U.S. Pat. 339,545 of 1886, whereby the fractionation of the materials is also attained. The authors claim that it provides an improved method of fractional distillation, yielding uniform fractions, and securing regular treatment of the crude substances, without waste of heat, time and material. The apparatus consists of either a vertical coiled-pipe retort or of one having a direct course, the former being preferable. It contains as many different chambers as the desired number of fractions, the successive sections being divided by partitions each a little below the preceding one, and arranged in separate spaces of the furnace. Each bend of the coil has attached a goose neck provided with a condenser, which discharges into a trough by means of a pump, the latter being also used to diminish the internal pressure, whence the distillate may be run off into any suitable receptacle. The sections are heated either by one furnace placed below, by separate fires in each compartment, or by steam. The heat of the furnace gases may be utilised as they pass up the flues on either side for heating the various sections, the temperature being controlled by means of dampers and air passages. As the heavier products require more heat, the successive sections may be made longer, but provided the temperature of each section is kept higher than that of the one above it, they may all be of one length. The oil is continuously introduced by a feed pipe into the highest section in a stream, and is converted into spray by an impinging jet of steam. The liquid circulates through the different sections, which are divided by traps to keep back the vapour, the latter

passing into the condenser. The oil after passing the trap encounters another jet of steam, and so on through all the sections, the temperatures of which are regulated according to the fractions required. No carbonisation takes place in the last section, as it discharges any heavy oil remaining unvaporised into a tar still. Although the feed is generally continuous, it is desirable in some cases that it should be intermittent. The essential feature of the invention lies in the fact that so large a surface of oil is exposed to the temperature of a given section, and thereby local heating avoided, that the uniformity of the fraction is assured. For refining such materials as are to be turned out in one product, steam jets are only used in the upper sections of the retort. —A. R. L.

Improvements in Distilling Crude Petroleum, Mineral Oil, Tar, and the like, and in Apparatus therefor. M. Böhm, Přívoz, Moravia. Eng. Pat. 327, January 7, 1891. 6d.

THE object of this invention is to utilise the heat, contained in the vapours from the still, for the preliminary heating of the material to be distilled. The apparatus consists of a tank provided with a worm, and is filled from the bottom with the oil to be heated, the latter being then conveyed to the still by an outlet pipe near the top. It has also a discharge pipe, fitted with a cock, on the bottom, and a cone or still head on the top. The vapours as they leave the still on being led into the worm, thus communicate their heat to the oil in the tank and partially condensing meanwhile, pass into a condenser placed below; whilst any of the oil which may become vaporised passes through the still head into a second condenser. —A. R. L.

IV.—COLOURING MATTERS AND DYES.

A Study of Certain Triphenylmethane Derivatives. E. Noetting. Bull. Soc. Ind. Mulhouse, 1890, 98-100.

Noetting and Polonowsky have found that tetramethyldiamidobenzhydrol combines with para-substituted amines, such as *p*-toluidine, *m*-xylydine, and pseudocumidine, the condensation taking place in the *m*-position to the amido-group when sulphuric acid is used, and in the *o*-position when hydrochloric acid is the condensing agent. Thus, with *p*-toluidine, according to the method used, there is obtained—

The first compound gives on oxidation a blue-green dye; the second does not oxidise regularly unless acetylated, when it gives a very bluish-green dye.

Noetting and Sharinsky in a similar way have condensed *p*-nitrodimethylamidobenzhydrol with *p*-toluidine, and are studying the derivatives of the compounds obtained.

The same chemists, by the action of the three nitrobenzaldehydes on dimethyl-*m*-toluidine, have prepared corresponding nitro-tetramethyldiamidoditylphenylmethanes—

All three compounds, on oxidation, yield green colouring matters. Kock previously prepared the leuco-base of one of these compounds, but did not oxidise it. The amido-

derivatives prepared by the reduction of these compounds give on oxidation differently-coloured compounds; thus, the para-compound gives a violet, the meta-compound a green dye. The ortho-compound cannot be directly oxidised: after acetylation, it yields a green-blue dye.

Dimethyl-*m*-toluidine thus behaves exactly like dimethylaniline as regards condensation with the isomeric nitrobenzaldehydes. It does not, however, like the latter, form a colouring-matter when oxidised in presence of *p*-toluidine.

By the condensation of nitrodimethylamidobenzhydrol with *m*-toluidine and dimethyl-*m*-toluidine, there are respectively obtained—

and

Both, on oxidation, yield green dyes.

Noelting and Trautmann have prepared hexamethyltri-amidotritolylmethane—

by condensing dimethyl-*m*-amidotoluidine with ethyl orthoformate, $\text{CH}(\text{OC}_2\text{H}_5)_3$. It oxidises to a blue dye.

Noelting and Freyes condensed together tetramethyldiamidobenzhydrol and *o*-toluylenediamine, obtaining the compound—

On oxidation it forms a blue-green dye. By treating this dye with phenanthraquinone, an azine, which is oxidisable into a green dye, is obtained.—E. B.

Examination of New Hydroxyanthraquinone Dyes.

L. Gattermann. Meeting of the Chemical Society, Heidelberg, January 23, 1891. Chem. Zeit. 15, 150.

On treating alizarin with strongly fuming sulphuric acid, tetrahydroxyanthraquinone is produced, the sulphuric anhydride of the fuming acid acting as an oxidising agent and becoming converted into sulphurous anhydride. The dye-product, which has been named *Bordeaux*, is identical with Liebermann's quinizarin, and its constitution is therefore—

It yields a nitro-derivative crystallising in dark black-green needles and by the reduction of this, amido-bordeaux is obtained. When quinizarin is treated with fuming sulphuric acid, a product identical with Bordeaux and quinizarin is obtained, and this may be taken as a further indication of the para-positions of the hydroxyl groups introduced when alizarin is converted into Bordeaux. Methylbordeaux has likewise been obtained from methylquinizarin. A penta-hydroxyanthraquinone is prepared from Bordeaux by oxidising its solution in sulphuric acid by manganese dioxide. It is known in trade under the name Cyanine R, and forms magnificent dark bronze-coloured scales. A hexahydroxyanthraquinone is obtained when Bordeaux is treated at a high temperature with ordinary concentrated sulphuric acid, and the same product is also formed when anthraquinone is treated during some days with pure sulphuric anhydride.

The reaction described above can be extended to nearly all the hydroxyanthraquinones, purpurin, for instance, yielding a tetrahydroxyanthraquinone isomeric with Bordeaux.—A. K. M.

The Induline Group. O. Fischer and E. Hepp. Annalen, 1890, 262, 237—264.

Rosindulines.—The formation of these dyes has been previously described (Annalen, 256, 233; this Journal, 1889, 877). The best yields are obtained when the intermediate product—the quinone-anilides—are produced in but small quantity, as it is only in the nascent state that these yield rosindulines. A low temperature and the presence of diluents will increase the yield of quinone-anilide. In the formation of phenylrosinduline from benzene-azo- α -naphthylamine and aniline, benzene-azo- α -phenylnaphthylamine is first formed, and can be detected during the first phase of the reaction by the blue solution it yields with concentrated sulphuric acid, phenylrosinduline giving a green solution. A small quantity of a new rosinduline, $\text{C}_{38}\text{H}_{26}\text{N}_4$ (anilido-isomaphthylrosinduline) has also been obtained from the melt and remains undissolved when this is boiled with benzene; it forms bluish violet salts and yields a green solution with concentrated sulphuric acid, from which water throws down an indigo-blue precipitate. The base crystallises from xylene in needles having a bronze lustre. When it (1 gm.) is heated with concentrated hydrochloric (20 grms.) and glacial acetic acids (10 grms.) at 180—200° for about 10 hours, it splits up into aniline and a rosindone which is a hydroxy-derivative of isomaphthylrosindone; this reaction is shown in the following equation, which also indicates the probable constitution of the anilido-isomaphthylrosinduline—

On heating amido-azo- α -naphthylamine hydrochloride (one part) with aniline (two parts), and aniline hydrochloride (one part) a mixture of *phenylrosinduline* and *isomaphthylrosinduline* is obtained, and their separation is effected by crystallisation from a mixture of benzene and alcohol. The isomaphthylrosinduline is identical with the product previously obtained from benzene-azo- α -dinaphthylamine, and its constitution is therefore—

Heated with concentrated sulphuric acid it yields a very sparingly soluble sulphonic acid, the salts of which are also but very slightly soluble in boiling water. When the sulphonic acid is heated with water under pressure at 200° it splits up into the corresponding rosindone and metamido-benzenesulphonic acid. The rosindone is converted by sulphuric anhydride into a readily soluble sulphonic acid, which dyes silk a beautiful yellowish red, and exhibits a red fluorescence. Monobromosindone and its sulphonic acid also produce magnificent eosin shades with strong fluorescence. The colours are comparatively fast.

Rosindonic acid, $\text{C}_{22}\text{H}_{14}\text{N}_2\text{O}_6$, is produced when rosinduline or its sulphonic acid, or rosindone is oxidised by chromic acid in acetic acid solution. It is insoluble in water, sparingly soluble in alcohol, and readily in ether and benzene; it melts at 209°. It is a monobasic acid and of the two possible formulæ—

and—

the authors consider the second the more probable as the substance does not react with hydroxylamine.

When orthonitrophenol (1 part) and aniline (2 parts) are boiled with 50 per cent. acetic acid (10 to 20 parts) for some hours, an abundant separation of *dianilidoquinone-anil* is obtained—

This product is identical with the substance obtained by Zincke and Hagen (Ber. **18**, 785) from the action of quinone on aniline and apparently also with the supposed hydroxy-azophenine obtained by Kohler (Ber. **21**, 910) from parnitroso-methoxydiphenylamine, and by the authors (this Journal, 1888, 316) from dibromonitrosophenol.

The azophenine of paratoluidine was first prepared by Kimich (Ber. **8**, 1031); its formula, however, is—

and not $\text{C}_{10}\text{H}_{17}\text{N}_3\text{O}$ as assumed by Kimich. The authors name it *paratoluidiazophenine*. When it is heated with wood spirit and sulphuric acid it splits up into paratoluidine and diparatoluidoquinone.

Azotoline.—The authors assign this name to a substance obtained by Nolting and Witt (this Journal, 1884, 248), from orthamidazoletolene and paratoluidine, and called by them the azophenine of paratoluidine. It is found that when this substance is boiled with wood spirit and sulphuric acid, it suffers a decomposition similar to that of azophenine and a ditoluidotoquinone.

is produced. Azotoline should accordingly have the constitution—

Amidophenylinduline, $\text{C}_{22}\text{H}_{18}\text{O}_4$ (D. R. P. 50,534); when this is heated with concentrated hydrochloric acid under pressure at 150°, it yields ammonia, aniline, and a substance soluble in alkalis (this last product differing in this respect from the product obtained from the induline $\text{C}_{21}\text{H}_{17}\text{N}_3$). *Phenylinduline*, $\text{C}_{21}\text{H}_{17}\text{N}_3$, is obtained by diazotising amido-

phenylinduline and boiling the product; it melts at 230°—231°, and is found to be identical with a substance obtained by the action of hydrochloric acid on azophenine and which was previously described as *anilidoquinonedianil* (Annalen, **256**, 261). The formation and properties of phenylinduline point to the constitution—

The authors have also examined Cassella's *indazine* obtained by the action of nitrosodimethylaniline on diphenyl-metaphenylenediamine. The purified base has a composition agreeing with the formula—

—A. K. M.

Alkyl Hydroxy-Derivatives of Dimethylaniline. E. Grimaux. Compt. Rend. **112**, 290—292.

CARBOXYL chloride reacts with meta-methoxy- or ethoxy-dimethylaniline—

in presence of aluminium chloride to form a blue colour, of great tinctorial power, which gives a good, pure blue with silk and wool and with cotton when mordanted with tannic acid. Heated with sulphuric acid to 100° C. a red fluorescent colouring matter results, resembling the product obtained by the action of dehydrating agents on dimethyl-meta-amidophenol.

The blue colour has not been analysed, but from its mode of formation it is in all probability a tri-ethoxy-hexa-methyl rosaniline, having the formula—

Hence by the introduction of the ethoxy groups into hexa-methyl rosaniline, the colour is changed from violet to blue.

Meta-ethoxy-dimethylaniline yields a nitroso-compound which behaves similarly to nitroso-dimethylaniline with most reagents. It forms hydroxy-azines with gallic and tannic acids, pyrogallol, orcinol, and resorcinol; eurhodines with meta-diamines and an indophenol with α -naphthol, but it does not react with β -naphthol to form an analogue of Meldola's blue, nor does it yield a methylene blue derivative by suitable treatment. With phthalic anhydride alone the base does not react, but in the presence of zinc chloride or of sulphuric acid condensation takes place, with the formation of a fluorescent red colouring matter which appears identical with rhodamine. In this reaction and in some others the ethoxy group appears to be changed to the simple hydroxy group, and the reaction takes place as with dimethyl-meta-amidophenol. This is also the case when the base is heated with arsenic acid to 175°, when a rose-coloured condensation product results. With phthalyl chloride a green colour is formed, with dimethyl-meta-amido benzoic acid a blue colour, with chloroform and caustic soda a red colour, whilst the acid chloride of benzene sulphuric acid, benzaldehyde, zinc chloride, and benzo-trichloride also give colour reactions.

Ortho-ethoxy-dimethylaniline (ortho-dimethyl-anisidine) boils at 210°—212° C. Its behaviour towards reagents is quite different to that of the meta-compound. It does not react with carbonyl chloride, chloroform and caustic soda, benzaldehyde or benzo-trichloride, nor does it yield a nitroso compound, resembling, therefore, dimethyl-ortho-

toluidine. When the base is heated with arsenic acid to 175° C., or with the acid chloride of benzene sulphonic acid, or by simply heating the hydrochloride of the base alone to 175°—180° C., a beautiful blue colour is produced.

Neither the meta- nor the ortho-base are oxidised by chloride of copper with the formation of a colour, on the lines of the production of methyl violet from dimethylaniline.

The author has also commenced the study of the behaviour of the nitro-derivatives of the above bases with reagents.

PATENTS.

Improvements in the Manufacture and Production of Sulpho-Acids of a Red Basic Naphthalene Colouring Matter. J. Y. Johnson, London. From the "Badische Anilin und Soda Fabrik," Ludwigshafen-on-the-Rhine, Germany. Eng. Pat. 6875, May 3, 1890. 6d.

This is an extension of Eng. Pat. 15,259 of 1888 (this Journal, 1889, 877), and describes the preparation of sulphonated derivatives of the *Rosinduline* series by treating sulphonated derivatives of the compounds mentioned in the previous patent with aniline and its hydrochloride. Substances belonging to the following classes are suitable for the purposes of this invention. (1.) Sulphonated derivatives of α - and β -naphthoquinone. (2.) Nitro-naphthol sulphonic acids. (3.) Nitroso-naphthol sulphonic acids. (4.) Azo-compounds from aniline, &c., combined with naphthol and naphthylamine sulphonic acids. In all these cases one sulpho group in the naphthalene must at least be heteromolecular to the amido-, nitro-, nitroso-, azo-, or hydroxy-groups. In order to test the suitability of a compound for the purposes of this invention, it is advisable to heat a certain quantity of it with twice its weight of aniline hydrochloride and three times its weight of aniline, raising the melt from 140° C. to 180° C. in about 8 or 10 hours. Tests are taken out at intervals, and after saturation with hydrochloric acid, are extracted repeatedly with dilute hydrochloric acid until the whole of the aniline is removed. If the residue dissolve to a green solution in concentrated sulphuric acid, the substance can be employed for the production of colouring matters, according to this invention. The sulphonic acids obtained may be further sulphonated, yielding colouring matters which dye animal-fibres red. The following is an example of the application of this invention. About 50 kilos. of amido-naphthoquinone-imide sulphonic acid (di-imido-naphthol sulphonic acid), 50 kilos. of aniline hydrochloride, and 175 kilos. of aniline are heated in an enamelled vessel to 150° C., the temperature after about three hours being raised to 160° C., and kept at this until the melt becomes no greener on dissolving in strong sulphuric acid. The melt whilst still warm is poured into 200 kilos. of 30 per cent. hydrochloric acid, 1,000 litres of water being afterwards added, when the whole is boiled mixed with 2,000 litres of water, cooled, filtered, washed, and pressed. In order to purify the acid it is converted into its sparingly-soluble sodium salt. The acid cannot be used for dyeing purposes, on account of its insolubility, and requires to be sulphonated, which may be performed by means of fuming sulphuric acid, when, according to the temperature employed, different sulphonic acids may be obtained. These acids dye animal-fibres bluish shades of red.—T. A. L.

Improvements in the Production of a New Hydroxyquinone and the Utilisation of the same in Dyeing. R. Holliday, Huddersfield. Eng. Pat. 7421, May 13, 1890. 6d.

By fusing Armstrong's sodium naphthalene disulphonate with caustic soda for a longer time than is necessary to produce dihydroxynaphthalene, it is converted into a hydroxyquinone which after conversion into its nitroso

compound can be employed with various mordants for dyeing purposes. Wool can be dyed black by treating it alternately with this nitroso-hydroxyquinone and chromium and iron salts.—T. A. L.

Improvements in the Manufacture and Production of Colouring Matters. J. Hall, Manchester. Eng. Pat. 8215, May 27, 1890. 6d.

DEHYDRO-THIO-*p*-TOLUIDINE or its sulphonic acid, when diazotised, will combine with azo-compounds of which *m*-phenylene diamine, *m*-tolylene diamine or resorcinol are constituents. A colouring matter which dyes unmordanted cotton a red shade of brown is produced by diazotising naphthionic acid and combining it with *m*-phenylenediamine and afterwards adding the diazo-compound from dehydro-thio-*p*-toluidine sulphonic acid. The dyestuff thus formed is salted out, filter-pressed and dried. The colouring matter may also be produced by combining the diazo-compound of dehydro-thio-*p*-toluidine sulphonic acid with *m*-phenylene diamine and afterwards adding the diazo-compound of naphthionic acid. A darker shade of brown is produced by using amido-azo-naphthalene disulphonic acid instead of naphthionic acid and a similar effect by using *m*-tolylene diamine instead of *m*-phenylene diamine. Yellower shades are obtained by the use of resorcinol.

—T. A. L.

Production of a Yellow Colouring Matter. O. Inray, London. From the "Farbwerke vormals Meister, Lucius, und Brüning," Höchst-am-Main, Germany. Eng. Pat. 8506, June 2, 1890. 4d.

The colouring matter is obtained by the action of a salt of tetrazodiphenyl on an alkaline solution of *o*-cresotic acid.

—T. A. L.

Improvements in the Production of Colouring Matters. O. Inray, London. From the "Society of Chemical Industry," Basle, Switzerland. Eng. Pat. 10,047, June 28, 1890. 6d.

THESE are colouring matters belonging to the rhodamine series, and are obtained by heating the condensation product of resorcinol and succinic acid (resorcinol-succineine) with secondary amines at a high temperature. The end product of the reaction, if dimethylamine be employed, is tetramethyl-*m*-amido-phenol-succineine or succinic acid rhodamine, whilst succinic acid rhodaminol is formed as an intermediate product, the latter having both basic and acid properties. 13.2 kilos. of resorcinol-succineine and 13.8 kilos. of a 40 per cent. solution of dimethylamine are heated with 70 kilos. of alcohol in a closed vessel at 170—200° C. for 14 hours. The melt is then diluted with water and heated on the water-bath with 21.9 kilos. of 33 per cent. soda-lye until the alcohol and excess of dimethylamine are driven off. The alkaline solution is then extracted with ether or toluene, and the succinic acid rhodamine separated from this solution by dilute hydrochloric acid or hydrochloric acid gas in the form of its hydrochloride as a green glistening crystalline mass. It dyes cotton and silk pink, the latter showing a vermilion-red fluorescence. The sodium salt of the succinic acid rhodaminol is precipitated from the alkaline solution by the addition of salt, forming a reddish-brown mass. Both the sodium and potassium salts are easily soluble in water, and dye silk a light pink from a soap-bath.—T. A. L.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

The Action of Copper on the Resistance of Colours to Light. A. Scheurer. Bull. Soc. Ind. Mulhouse, 1891, 82—84.

THE author has studied the action of copper oxide on the light-resisting properties of the phenolic colouring matters. For this purpose medium shades of the following colours were printed by block on white calico: Persian berry yellow (fixed with alumina), Alizarin-blue (chrome), Alizarin-blue (nickel), Alizarin-maroon (chrome), Anthracene-brown (chrome), Naphthazarin-grey (chrome), M G Orange (chrome). Each fent was then divided into four parts. One portion was not further treated, being used for comparison (set No. 1). Another portion was boiled for 10 minutes in a solution containing per litre of water 24.9 grms. of copper sulphate and 10 c.c. of strong ammonia liquor (set No. 2). The third set was passed through gum tragacanth mucilage (30 grms. per litre) and dried; and the fourth set was prepared in a mixture of a solution of 20 grms. of copper sulphate in 480 grms. of gum tragacanth mucilage and 500 grms. of the same mucilage to which 20 c.c. of ammonia liquor had been added. All four sets of fents were exposed to the sun for a month (August) with the following results:—The colours of set 4, with the exception of M G Orange, were not affected; set 2 suffered to some extent; sets 1 and 3 were much bleached, M G Orange, in both cases, being quite decolourised; a little protection was exercised at the commencement of the exposure by the gum tragacanth paste on set 3, but at the close of the experiment this set was as much decolourised as set 1. It was also ascertained that copper oxide, whether precipitated directly in the fibre or applied superficially by suspension in a thickening agent, greatly increased the fastness to light of basic dyes fixable with tannic acid, and also of indigo.

The author concludes that:

1. The protective action exercised by copper on the fastness to light of colours is a general one for all colours.

2. This action is not necessarily due to a combination of the copper oxide with the colouring matters or lakes.

3. Intimate contact of the copper oxide with the colour-lakes is unnecessary.

4. All that is necessary for the preservation of colours from the action of light, is to have a thin layer of copper oxide over them, the actinic rays being incapable of penetrating through such a layer.—E. B.

Note on Mimgite, an Indian Dyewood. A. Feer. Bull. Soc. Ind. Mulhouse, 1891, 85—86.

THE dyewood is found to closely resemble munjeet in appearance and properties, and is presumably identical with the same. It consists of brown, friable sticks, 3 to 5 mm. thick, which are very vascular and traversed by a central cavity. An extract of the colouring matter was made and its properties determined. Alcohol alone being found incapable of extracting the colouring matter, alcohol containing 10 per cent. of strong hydrochloric acid was used. The alcoholic solution was concentrated, the colouring matter precipitated by addition of water, collected on a filter, washed, and dried at a low temperature. 100 parts of powdered mimgite yielded in this manner 7.5 parts of a yellow powdery extract. The colouring matter is insoluble in water, dissolves in organic solvents with a brown colour and in alkalis with a violet-red. Its smell recalls that of madder. At a high temperature it sublimes in orange-needles. To test its dyeing properties, it was dissolved in a little alcohol before adding to the dye bath. On the alumina mordant it gave a red, on iron violet, and on chrome a purple-rose. There is considerable difference in the shades dyed with the extract and with the wood itself, the former being more yellow and less fast to soap than the latter, which closely resemble those of alizarin. From this it would seem that acidulated alcohol extracts a yellow colouring

matter which stays in the wood in the ordinary operation of dyeing. These differences in the dyeing properties of mimgite and its extract are similar to those of madder and garancine.

As regards the colouring power of the extract of mimgite, 0.75 grm. of the same was found equivalent to 1 grm. of 20 per cent. alizarin paste.—E. B.

Dyeing with Aniline Black and Smoothing of the Cotton Warp. Oesterr. Wollen u. Leinen Industrie, 1891, 11, 4.

THE dyeing and oxidising is performed on machines constructed like those used in hot-air drying, but provided with four rollers in four separate troughs. The material is passed consecutively through troughs containing Turkey red oil kept at a temperature of 40°, a cold concentrated solution of copper sulphate and twice through a solution of aniline salts and sodium chlorate ("strength 5°"), the excess of liquor being each time removed before the material enters the next trough. It is now passed over the hot-air dryers, and then on to the usual smoothing machines with rollers for drying. Finally it enters a solution of sodium bichromate heated to 40° and after squeezing the excess of liquor off, and washing the sizing is applied. The troughs must be frequently refilled with solutions of the same strength. The Turkey red oil and sodium bichromate are used up fastest. The copper sulphate bath is kept up to strength by leaving crystals of the salt at the bottom of the vat.—A. R.

Researches on Turkey Red Oil. Scheurer-Kestner. Compt. Rend. 112, 158—160 and 395—397.

See under XII., page 171.

VII.—ACIDS, ALKALIS, AND SALTS.

Arsenic in Commercial Acids. G. Buchner. Chem. Zeit. 15, 13.

ACCORDING to the author a determination of arsenious acid in 100 kilos. of English oil of vitriol showed 131 grms. of As_2O_3 , so that a carboy containing 120 kilos. would contain as much as 157 grms. Commercial hydrochloric acid showed in 100 kilos. of acid 592 grms. of As_2O_3 .—T. L. B.

Observations on Apparatus for the Concentration of Sulphuric Acid. W. C. Heraeus. Chem. Zeit. Rep. 15, 36.

IN a pamphlet on this subject the author observes that there exists a generally adopted belief in the superiority of the purest platinum as the material for constructing vessels for concentrating sulphuric acid. To put this view to the test the author alloyed pure platinum (containing only 0.01 per cent. iridium), with 5 per cent. and 10 per cent. of iridium, and rolled the alloy into sheets which were then placed, together with a sheet of the pure platinum, for 40 days in a concentration apparatus in which a 98 per cent. acid was manufactured. Taking the loss in weight of the pure platinum in this experiment as 100, the 5 per cent. iridium alloy lost 73 and the 10 per cent. alloy only 58, thus showing an important advantage in favour of platinum-iridium alloys as a material for constructing concentration apparatus. In further experiments on the resisting power of gold in a similar capacity, still more favourable results were obtained. Taking the loss in weight of pure platinum again as 100, commercial platinum (containing 0.5 per cent. iridium) lost 90, the 10 per cent. iridium alloy lost 58, and pure gold only 13, that is one-seventh the loss sustained by the material usually employed for concentration purposes. A gold solder

must therefore be greatly superior to a platinum solder in the construction of apparatus, and in view of these facts the author has patented a process for covering the surface of platinum vessels with a compact adhesive layer of gold on those parts in contact with acid during concentration. As only 144 grms. of gold at 2,800 marks per kilo. go into solution against 1,000 grms. of commercially pure platinum at 1,800 marks per kilo. under the same conditions, the coating of concentration apparatus internally with gold offers considerable pecuniary advantages.—G. H. B.

Remarks on Luedecke's Heintzite. W. Feit.
Chem. Zeit. 15, 115.

THE author considers that the mineral found by Luedecke in a piece of pinnoite from Leopoldshall and named by him heintzite is in reality identical with kaliborite, which was discovered by Feit in Schmidtmannshall, near Aschersleben (this Journal, 1889, 882). The differences in the analytical numbers of the two experimenters may be explained by their having adopted different methods of analysis:—

	Luedecke.	Feit.
K ₂ O	7.39	6.48
MgO	12.23	12.06
B ₂ O	60.53	57.46 (by difference)
H ₂ O	19.85 (by difference)	21.00
	100.00	100.00

The author maintains that his method of determining the water and calculating the B₂O₃ by difference is preferable to the determination of the latter as conducted by Luedecke. He finds that the loss on ignition is the same whether the mineral be heated alone or with magnesia, and from this he concludes that the loss is due solely to water and not in part to the volatilisation of boric acid.—A. K. M.

On the Sodium Bichromate of Commerce. R. Kissling.
Chem. Zeit. 15, 373.

THIS substance is met with in trade in three forms: 1. In small crystals containing two molecules of water of crystallisation; 2. In lumps or powder of the fused substance containing less water; 3. In larger crystals. The first form is very convenient to use, but its manufacture has become somewhat restricted, owing to the impression that it more readily deliquesces on exposure. The author combats this assumption and gives figures to show that the rate of absorption of moisture on exposure of all three forms is not sensibly different, but admits that the initial larger quantity of water in the crystals hastens the period of incipient deliquescence. After 23 days' exposure over 60 per cent. of water had been absorbed in each case. Determinations of the actual amount of bichromate in samples from several sources were made by titration with iron solution, using ferrieyanide as indicator.

—G. H. B.

On the De Wilde-Reychler Chlorine Process. K. W. Jurisch. Chem. Ind. 14, 151—155.

REFERENCE to this process has already appeared (this Journal, 1890, 510) in an abstract of the patent specifications concerned. The present article describes the results of laboratory work and of experiments on a semi-industrial scale. The object of the process is to render practicable the decomposition of magnesium chloride by air with the evolution of chlorine, and the modifications consist in the use of magnesium sulphate to give coherence and porosity to the mass, and of manganese to favour the evolution of chlorine. The initial mixture corresponds to the formula $MgSO_4 + MgCl_2 + MnCl_2$, which on gradual heating loses water of crystallisation, and subsequently at a low red heat evolves chlorine and leaves a coherent porous black substance which plays the part of intermediary in the reaction $2 HCl + O = H_2O + Cl_2$. The experimental apparatus comprised: 1, a vessel for the production of hydrochloric acid gas from the crude acid and hot sulphuric acid; 2, a superheater for the acid gas; 3, a superheater for air; 4, a decomposer to hold the active substance, and consisting of an upright clay cylinder with an internal diameter of three-quarters of a metre; 5, a scrubber for absorbing undecomposed hydrochloric acid gas; 6, four absorbers for the production of bleaching liquor; 7, a suction pump to draw the gases through the apparatus. For the first series of experiments a decomposer holding 900 kilos. of material was used, but this was afterwards substituted by one holding 2,800 kilos. of material arranged in layers on three perforated plates to allow of easy penetration of the gases. Starting with the black material in the oxidised state, hydrochloric acid gas at a temperature of 425° to 525° C. is sent into the decomposer, where it is absorbed by the material to saturation, about one-fourth of the gas being decomposed in this part of the process and evolved as free chlorine. The fully chlorinated material has then become white in colour, and the stream of acid gas is changed for a current of heated atmospheric air, the oxygen of which causes the evolution of chlorine, which continues until the material has resumed a black oxidised condition. During the chlorination period of the process the evolved gases contained 20 to 30 volumes per cent. of chlorine, the rest consisting of atmospheric air and oxygen. During the oxidation period the gases contained 18 to 20 per cent. of chlorine and 1 to 2 per cent. of hydrochloric acid, but this proportion decreased rather rapidly after the fourth hour of work down to 4 per cent. of chlorine at the eighth hour and end of the oxidation. The hydrochloric acid accompanying the evolved chlorine was removed by washing with water in the scrubber, and the chlorine was used for the production of bleaching liquor. The improvised character of the experimental plant left much to be desired as to a due proportion in the capacities of the various parts, and in this direction a great improvement in the amount of duty remains to be effected. As an actual result the 2,800 kilos. of material gave a production equal to 800 kilos. of bleaching powder in 24 hours, a quantity which would be doubled in the same time in more suitably proportioned plant. By utilising authoritative statements of cost of production, notably those of Hasenclever, for similar operations on the large scale, the author arrives at the figure of 229.3 frs. for one ton of chlorine when the hydrochloric acid is purchased, and 137.9 frs. per ton when the acid is produced on the spot. The statement occurs that a French manufacturer places the cost of producing one ton of chlorine by the Hurter and Deacon process at 150 frs. The essential advantages of the process under consideration are, that the apparatus is small and cheap, both to erect and maintain, and that the chlorine gas is so concentrated as to offer no difficulty in the manufacture of strong bleaching powder, whilst an ordinary workman is enabled, by the simplicity of the operations, to adequately fulfil the conditions of successful application.—G. H. B.

On the Amide of Sodium and the Chloride of Disodammonium. Joannis. *Compt. Rend.* **112**, 392—394.

SODAMMONIUM becomes decomposed spontaneously at the ordinary temperature into hydrogen and the amide of sodium, NH_2Na . The decomposition is always very slow (about 0.35 cc. per 24 hours for 1 grm. of substance), and tends to approach a limit as the pressure of the disengaged hydrogen increases. The evolution of hydrogen is accompanied by the gradual formation of transparent colourless crystals about 1 mm. in breadth. These crystals are the amide of sodium and differ in appearance from those obtained by Gay-Lussac's method, which gives a blue or green amorphous mass. The crystals dissolve in water with a hissing noise, but no gas is given off and the solution contains only soda and ammonia.

Sodium chloride reacts on sodammonium, but does not produce the sub-chloride described by Rose. When sodium chloride and sodammonium are brought together in saturated solution, the disengagement of hydrogen rapidly increases to such a degree that it is difficult to get a measurement of the evolved gas owing to premature destruction of the apparatus employed. At the end of the reaction the solution has a red, brown, or blue colour owing to excess of sodammonium when so much has been used; but if sodium chloride is in excess the resulting solution is colourless, and if the white product be washed with liquid ammonia the excess of sodium chloride becomes removed and what remains is amide of sodium, which is, in fact, most readily prepared in this way. The reaction described above is due to the formation of disodammonium chloride, $\text{NH}_2\text{Na}_2\text{Cl}$, an unstable substance from which liquid ammonia dissolves out the sodium chloride, whilst water decomposes it quickly into soda-ammonia and sodium chloride. Its composition as expressed in the above formula was satisfactorily arrived at by indirect methods of analysis.

—G. H. B.

Works for the Automatic Supply of Brine at Syracuse. U.S. C. B. Brush. *Trans. Amer. Soc. Civil. Eng.* **23**, 1890, 95; *Proc. Inst. Civil. Eng. Abs.* **103**, 63.

THE old salt works at Syracuse, which at one time were the largest in the country, had experienced a great falling off in their production, owing partly to the exhaustion of their natural supply; and to resuscitate the industry, the Tully Pipe-line Company have established works for the constant supply of water saturated with salt.

The brine is delivered at Syracuse into an open reservoir of 5 million gallons, the fresh water being obtained by a gravitation supply from the Tully Lakes, at a distance of 23 miles from the city, and converted into brine during its passage to Syracuse by passing it through wells sunk into the beds of rock-salt.

From the source of supply, which is about 800 feet above the level of the reservoir, the fresh water is conveyed in a 12-inch main; and the wells are located on its course, at a distance of three miles from the source, where the ground is about 400 feet lower. At this point 12 wells have been sunk into the beds of rock-salt, which are found at a depth of 1,200 feet below the surface. The first bed has a thickness of 13 feet, and the second of 54 feet, the two beds being separated by a layer of slate rock, 25 feet thick.

The wells are arranged in three groups, about 1,000 feet apart, each group containing four wells placed at the corners of a rectangle, 400 feet by 150 feet. Each well consists of a 6-inch bore pipe, with an interior pipe 3 inches in diameter. The fresh water is led down to the rock-salt through the annular space, and returns through the central pipe as saturated brine. As the salt is dissolved, the cavity at the base of each well is enlarged, and the saturation becomes more rapid.

The brine rising from each well is stored in a regulating tank, having a capacity of 1 million gallons, and provided with a self-acting valve on the principle of an ordinary ball-cock, by which the admission of water from the main is controlled by the level of the brine. From these tanks the brine is conveyed by the 12-inch main to the Syracuse reservoir, which is also commanded by a self-acting valve of the same kind.

At every point the flow is automatically controlled, and is limited by the draw-off at the Syracuse reservoir. At the present time the supply is about 300,000 gallons per day with a saturation of 90 per cent., and it is expected that 95 per cent. of saturation will eventually be obtained.

PATENTS.

Improvements Connected with the Manufacture of Soda by the Ammonia Process. F. Ricard, Paris, France. Eng. Pat. 4394, March 20, 1890. 6d.

In the manufacture of soda by the above process a solution of chloride of ammonium is obtained. This is evaporated to dryness and heated with sea salt, and the volatilised chloride then mixed with manganese carbonate and again roasted, forming carbonate of ammonium and manganese chloride. By mixing the carbonate with brine the ordinary reaction is set up. The chloride of magnesium or calcium chloride, or other chloride, may also be employed. The chloride, when treated with magnesia and carbonic acid simultaneously, is reconverted into the carbonate, whilst the chloride of magnesium when dried and heated with steam is converted into the oxide with the evolution of hydrochloric acid gas. The carbonate can either be utilised afresh as above described, or by roasting converted into the peroxide, which can be employed in the manufacture of chlorine. Other applications of these methods are given.—S. G. R.

Improvements in or Connected with Apparatus used in the Distillation of Ammonia. J. J. and T. F. Meltrum, Manchester. Eng. Pat. 4434, March 21, 1890. 8d.

THE lime employed may be either slaked previously or else placed upon a sieve lying below the level of the water in a tank, the sides of which are sloping. The lime is kept thoroughly agitated by means of a pipe furnished with suitable apertures, through which is forced a current of steam or air, preferably the former. This tube is also fitted with a special steam pipe to clear both it and the perforations if they should have become blocked by the deposition of lime. The milk of lime is mixed with the gas liquor and fed into the still by means of an injector "with a central nozzle for introducing the milk of lime and a combining cylinder in which the two liquids flow together, the lime forming a central core and the ammonia liquor surrounding it." A still more thorough incorporation is obtained by causing the mixture to impinge upon a dash plate at right angles to the current, or by other similar devices. Where the plant is very small a pipe is provided by which a portion of the lime feed is returned to the supply tank. The pipe is then much less liable to become choked than with a small flow, whilst the lime is not fed in to excess. Drawings are attached to the specification.—S. G. R.

An Improved Process for the Production of Hydrate of Magnesia. H. Precht, Stas-furt, Germany. Eng. Pat. 4759, March 26, 1890. 8d.

MAGNESIA obtained by calcining magnesite is under ordinary conditions extremely difficult to hydrate. The patentee effects this more readily and rapidly by heating with water at 105° C. This is carried out either by using superheated steam, or water under steam pressure. In the latter case the mixture must be kept well stirred or the whole will set into a stone-like mass.—S. G. R.

Improvements in Treating Phosphatic Minerals. L. Mond, London. Eng. Pat. 5072, April 1, 1890. 4d.

ACCORDING to this invention the minerals which are to be treated are more particularly those containing phosphates and carbonates of lime, though the more inclusive range of "phosphatic minerals containing carbonates" is claimed. Such minerals are in the first place calcined so that the carbonates are eliminated or reduced. The resulting product

is mixed with water and treated with sulphuretted hydrogen, access of air being as much as possible excluded. The lime, of the carbonate of lime present, is thus converted into the soluble calcium hydrosulphide, $\text{Ca}(\text{SH})_2$, which is separated, and the insoluble residue, containing all the phosphates, is washed on suitable filters. To recover the sulphuretted hydrogen from the soluble calcium hydrosulphide obtained, the solution of the latter is treated with carbonic acid, itself derived by calcining the original mineral. Thus carbonate of lime is precipitated and sulphuretted hydrogen evolved, which is used "in treating a second batch of calcined mineral." To compensate any loss of sulphuretted hydrogen, some Le Blanc alkali waste may be added to the calcium hydrosulphide solution. It is also proposed to recover the sulphuretted hydrogen by heating or boiling the solution of calcium hydrosulphide for some time, sulphuretted hydrogen being evolved and hydrate of lime separated out. The residual solution, after removal of the hydrate of lime, and still containing a little sulphuretted hydrogen, is used in place of water for mixing up a fresh batch of the calcined mineral.

Thus some calcium hydrosulphide always remains in the liquor, and the second operation, in which a quantity of sulphuretted hydrogen equivalent to this hydrosulphide must be added, will yield the full quantity of sulphuretted hydrogen needed in the third operation, and so on, excepting small incidental working losses.

Improvements in the Preparation of Chlorine. G. E. and A. R. Davis, Manchester. Eng. Pat. 6416, April 28, 1890. *Sd.*

THE patentees point out that their invention is embodied in a process for manufacturing chlorine by means of nitric acid in which a minimum quantity of sulphuric acid is employed, sufficient merely to decompose the common salt necessary for the production of the hydrochloric acid, and to provide a means for the perpetual regeneration of the nitric acid used in the process. They incidentally point out that in Dunlop's process, Eng. Pat. 11,624 of 1847, in which common salt and nitrate of soda are treated with sulphuric acid, the probable cause of ultimate abandonment would be sufficiently explained by the fact that the manufacture of 35 tons per week of chlorine would require at least 2,000 tons of sulphuric acid in which to absorb the nitrous compounds formed.

The patentees separate their operation into three parts—

First.—What may be termed the salt-cake process, in which common salt or other suitable chloride, is treated with the sulphuric acid that has been used for absorbent purposes in other parts of the process.

Second.—The treatment of the hydrochloric acid gas with nitric acid in such a manner that the chloronitrous gases and oxides of nitrogen formed along with chlorine, interact in the presence of air, water, and nitric acid, with the ultimate production of chlorine, and reproduction of nitric acid; and,

Thirdly.—The absorption of any remaining oxides of nitrogen in strong sulphuric acid, leaving only chlorine mixed with air and nitrogen to pass on for utilisation.

With regard to the plant, any ordinary arrangements for making salt-cake and hydrochloric acid gas may be used. Preferably the mechanical salt-cake furnace described in Eng. Pat. 6433 of 1890, in which the fuel gases are kept out of contact with the hydrochloric acid gas, is used; besides and in connexion with this, there is used a series of "two or more towers packed with suitable material, down which nitric acid is made to flow, an absorbing tower for arresting traces of nitrous compounds, that have escaped the oxidising and other arresting influences in the previous towers, and a wash tower down which water is caused to flow."

The claiming clauses of this patent are as follows:—

1. The method of preparing chlorine from hydrochloric acid by the aid of nitric acid in the presence of air, in towers packed with suitable material, the nitric acid being employed to act as a carrier of oxygen from the air to the hydrogen of the hydrochloric acid without the necessity for refrigeration.

2. The utilisation of the water charged with impurities from the final wash tower (for washing the chlorine obtained in the process with water). This water is employed to preserve the nitric acid in No. 1 nitric acid tower at its normal strength.

3. The process of making chlorine, working only with one nitric acid tower, in which nitric acid is made to act as a carrier of oxygen from the air to the hydrogen of the hydrochloric acid.

4. The use of apparatus for preparing chlorine from hydrochloric acid, constructed substantially as described, in the manner and for the purposes set forth.

Improvements relating to the Preparation of Chlorine. G. E. and A. R. Davis, Manchester. Eng. Pat. 6331, May 3, 1890. *Sd.*

IN the previous specification, Eng. Pat. 6416 of 1890, it was shown how the last traces of nitrogen compounds, mixed with the chlorine, were absorbed in sulphuric acid. It was further stated that that sulphuric acid was then used to decompose a fresh batch of salt. The water formed during the reactions runs away from the first nitric acid tower holding in solution some hydrochloric acid gas. It has been found since filing the Patent 6416 of 1890, that such solutions of hydrochloric acid gas thus running away may contain as much as 30 up to 50 per cent. of the hydrochloric acid entering the tower, and the present invention is for the purpose of treating that aqueous solution in such wise that the hydrochloric acid gas may be retained in the system until it is converted into chlorine. This is accomplished by adding to the apparatus already described in Eng. Pat. 6416, 1890, a tank or partially closed vessel at a suitable level, so that the aqueous solution of acid running from the first nitric acid tower, and the sulphuric acid running from the absorbing tower can be led into it. These two liquids on mixing evolve much gas, and this is conducted from the tank into the nitric acid tower at a suitable height by means of pipes. The mixture must be continuous and regular, and the proper dilution with air secured. It is preferred to fit the tank or other receptacle with a diaphragm, dividing its lower section into two chambers, the smaller to serve as a mixing chamber, from which the commingled liquids overflow into a second or larger chamber where they are subjected to the action of the current of gases coming from the salt-cake apparatus. As an alternative process an extra tower, to be used as a drying tower, is interposed between the salt-cake apparatus and the first nitric acid tower. Down through this tower, packed with suitable material, one portion of the total nitrous-sulphuric acid, considered as being split into two streams, is allowed to run. Up the tower and meeting this acid the hydrochloric acid gas and air coming from the salt-cake apparatus, pass, and are dried, the sulphuric acid flowing to the salt-cake pot to work another charge of salt. The second stream of nitrous-sulphuric acid is meanwhile run into the divided tank first described together with aqueous hydrochloric acid coming from the first nitric acid tower.

Improvements in Apparatus for Recovering Soda and other Chemicals from Spent Liquors. L. D. Armstrong, Lock Haven, Penn., U.S.A. Eng. Pat. 18,187, November 11, 1890. *Sd.*

THE apparatus consists of a rotary evaporator constructed of a series of shells or cylinders arranged one within the other, and communicating with a suitable source of heat so that the products of combustion may come in direct contact with the liquor during its circuitous passage over the inner and outer surfaces of the cylinders.—S. G. R.

Improvements in the Production of Bicarbonate of Soda and Sulphuretted Hydrogen, and in Apparatus therefor. J. Leith, St. Helens. Eng. Pat. 21,078, December 7, 1890. *Sd.*

WHEN brine is heated under pressure with ammonium sulphide and carbon dioxide, sulphuretted hydrogen is evolved, and bicarbonate of soda and ammonium chloride

produced. The sulphuretted hydrogen is passed into a mixture of calcium sulphide and water, forming calcium sulphhydrate. This solution is mixed with the chloride of ammonium solution, from which the bicarbonate has been separated by filtration, and the two are heated, ammonium sulphide and sulphuretted hydrogen being given off and calcium chloride remaining behind in solution. The sulphide of ammonium is utilised as already indicated, whilst the sulphuretted hydrogen is burned to form sulphurous acid, or otherwise disposed of.—S. G. R.

VIII.—GLASS, POTTERY, AND EARTHENWARE.

Researches upon the Devitrification of Glass, and upon the Solvent Action of Water upon Glass. Monit. Scient. December 1890, 1229—1233.

Devitrification.—A microscopic examination of the crystals forming the core of the particles extracted from certain samples of devitrified soda-glass, shows that they consist of wollastonite or calcium bisilicate. *A priori*, it might be expected that such would be the composition of these crystals, because the alkaline silicates have as yet only been obtained in the wet way, and containing water of crystallisation, whilst double silicates of calcium and sodium or of calcium and potassium are not known to occur in nature. If, then, crystals be found in a glass made from lime and soda, they can only consist of calcium silicate (when, at any rate, the glass contains no aluminium, or only a trace of it).

If aluminium, magnesium, or oxide of iron be added to such a glass, it is possible, in certain cases, to obtain crystals of double or multiple silicates, containing two or more of these bases, and sometimes also sodium. Thus, crystals of albite (silicate of aluminium and sodium) have been found in a soda-glass. The aluminium existing in this glass was only found in small quantity, and had been introduced accidentally from the use of impure materials, and from the action of the materials upon the clay of the melting pots.

The formation of crystals of calcium silicate in glass leads one to conclude that ordinary glass ought not to be considered as a double silicate, but as a mixture of sodium silicate and of calcium silicate + acid, the calcium silicate being merely dissolved in the sodium silicate.

It is known that in the wet way, alkaline silicates are readily decomposed by salts of calcium, forming calcium silicate, the composition of which is dependent upon the composition of the alkaline silicate. If lime be added to a glass of soda and lime, not capable of devitrification, it takes up a certain amount of silica to form calcium silicate, thus increasing the proportion of the matter to be held in solution by the sodium silicate. By successive additions of lime, enough calcium silicate may be formed to saturate the sodium silicate. After this point is reached, crystallisation or devitrification may occur.

The addition of silica instead of lime produces the same result, although less rapidly. The silica acts by diminishing the proportion of alkali and by saturating a part of the alkali, consequently diminishing its solvent capacity upon calcium silicate.

A study of the various glasses made from lime and soda leads to the conclusion that a glass formed according to the following equation is least susceptible of devitrification:—

Expressed centesimally its composition is about:—

	Per Cent.
Silica.....	71·5
Lime (CaO).....	16·2
Soda (Na ₂ O).....	11·5
Alumina and oxide of iron.....	0·8
	100·0

An easily devitrifiable glass, on the other hand, has the following composition:—

	Per Cent.
Silica.....	75·7
Lime.....	14·5
Soda.....	9·0
Alumina and iron.....	0·8
	100·0

This corresponds to the formula—

It will be seen that the percentage of lime in the non-devitrifiable glass is greater than in the devitrifiable. This is explained by the fact that it is not the mere difference in quantity of lime that produces the difference between the two kinds of glass as regards their susceptibility to devitrification, but the property of devitrification is a function of the ratio of the sodium silicate to the calcium silicate + acid held in solution by the sodium silicate. This ratio is equal to 0·40 in stable glass, and in unstable glass it is—

$$\frac{Q + 13\cdot66}{62\cdot64 + 11\cdot5} = 0\cdot28.$$

The more the ratio decreases in value from 0·4, the more readily devitrifiable does the glass become; and this ratio can decrease in value only by increasing the quantity of lime or silica, or by diminishing the quantity of soda.

The above only applies to lime and soda glasses. The same principle holds good in the case of lime and potash glasses, but the ratio fixing the maximum of stability of the glass is probably different, due to the different solubility of calcium silicate in potassium silicate.

It is known that a saturated solution of one salt is still further capable of dissolving another salt. A similar property may exist in a glass containing several bases, and this would explain why glasses are the less easily devitrifiable the greater the number of bases they contain. It would also explain the stability of aluminous glasses, which can be worked to any extent without devitrification, although in them the earthy bases exceed in amount the weight of lime which in a simple lime glass would lead to rapid devitrification. Since the presence of several bases in a glass results in diminishing the tendency to devitrification, it would seem that glass-makers, when a colourless glass is not required, ought to try to produce glasses realising these conditions, more especially as they would thereby effect an economy of material, lime, magnesia, and oxide of iron, being much cheaper than potash or soda. It would be easy to procure a calcareous clay at a low price, of such a composition that it would only be necessary to add to it sand and a little alkali to make these stable multiple basic glasses. This is, in fact, what glass bottle makers do, and the stability of bottle glass which contains a comparatively small quantity of soda may be ascribed to the number of bases existing in the glass.

But for making colourless glasses, the glass-maker is thrown back upon the sole use of lime and soda as bases, and, by making the glass approximate to the composition above indicated, he will be able to make it but little susceptible to devitrification.

Solvent Action of Water upon Glass.—Mylins and Forestier having stated (Monit. Scient. 1890, 34) that water does not dissolve glass, but decomposes it into alkali and silicic acid, the authors have re-investigated the subject.

Three kinds of glass were used—blown glass, used for incandescent electric lamps, watch glass, and crown glass. The glasses were finely powdered and digested for eight hours at about 100° with a litre of distilled water in a platinum dish, the water being added in portions of 100 cc. at a time, so as to keep the level of the liquid about constant. After filtering the water to remove the suspended glass the water was evaporated to dryness. The weight of

the residue did not, however, represent exactly the weight of glass dissolved, as it was found to contain carbonic acid derived from the air, which had decomposed the dissolved silicate, forming a precipitate of gelatinous silica.

A determination of the dissolved alkalis was, however, made, and it was found that the incandescence lamp glass had yielded, per 100 parts of glass, 3.974 per cent. of soda; the watch glass, 2.076 per cent.; and the crown glass, 6.986 per cent. (+ 0.20 per cent. of sodium sulphate).

An attempt to estimate the dissolved silica in the case of the lamp glass gave—

	Per Cent.
Silica.....	0.134
Soda.....	3.974

or about one equivalent of silica to three of soda, so that the silicate dissolved by the water may be taken to be a tribasic silicate, $\text{SiO}_2 \cdot 3\text{Na}_2\text{O}$.—H. S. P.

Glaze for Earthenware Tubes. Thonind. Zeit. **14**, 754.

THE best plan is to employ a clay containing iron, which is either poured on to the tubes when they are about of the hardness of leather, or else allowed to run on whilst the tubes are rotated. The burning is conducted at a fairly high temperature. If blast-furnace slack is made use of the variation in its composition and the large percentage of calcium contained must be considered. The presence of calcium sulphide in the slag is to be avoided, as during the burning this is transformed into the sulphate and gives rise to bubbles in the glaze. It is necessary to mix the slag with sand and earthenware cement so as to make the glaze adherent.—C. A. K.

The Slate-Clay found in the Coal Measures of Bohemia. C. Bischof. *Spechsaal*, **23**, 1010.

THE author compares the properties of the valuable slate-clay of Bohemia with kaolin. They are both white, but the latter is looser, more voluminous and dry. Slate-clay is very dense, and on macerating with water, the water is not rendered so turbid as with kaolin. For technical purposes the slate-clay should contain only small quantities of sand and considerable quantities of alumina.—A. R.

PATENTS.

An Improvement in the Manufacture of Glass. J. G. Sowerby, Gateshead. Eng. Pat. 3286, March 1, 1890. *Sd.*

ORDINARILY such an article as a jug is made in several operations, "the handle, top, and lip are separately made, and the former attached to the body." By this invention the whole is made in one operation. The molten glass is poured into the body of the mould, a solid plunger lowered, and some of the molten material thus forced up so as to fill the handle, &c., in the case of such an article as a jug. Compressed air is then forced in through the ring round the plunger, blowing the glass out to the required shape and size, the escape of air being prevented by metallic springs which act as a packing to the plunger.—V. C.

Improvements in Kilns or Ovens for Firing Glass, Enamel-ware and for other Purposes, and in Annealing Devices. H. T. Parfitt, Lewisham. Eng. Pat. 4592, March 24, 1890. *Sd.*

THE kilns are heated by burners in which "atmospheric gas, water-gas, or the like" is used. The flame follows the curved roof of the kiln so that the products of combustion do not come into contact with the articles treated. Deflecting blocks are placed so that the flame does not pass directly to the flues. The products of combustion are employed to heat up a second chamber, usually placed above the first. The articles to be treated are placed on low trucks which

run on rails and can be drawn out without interrupting the process. These trucks are provided with moveable fire-clay partitions by means of which the size of the chambers can be reduced at will. When the truck is drawn out of the kiln a cover of iron wire quilted with asbestos is placed over it, forming an annealing chamber.—V. C.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

Preservation of Timber. J. W. James. *Proc. Inst. Civil Eng.* **103**, 1890—1891.

THE author's observations of the piles of a jetty and of railway sleepers at Port Darwin, South Australia, showed that the wood called "jarrah" resisted the attacks of the teredo better than "karri," but that "billian" (North Borneo ironwood) was preferable to either; it was also but little damaged by white ants. The belief that the teredo is killed by the removal of the timber in which it is from the water, and exposure to the sun for 48 hours is erroneous, specimens of the insect alive, though feeble, being obtained from timber that had been exposed to a tropical sun for two months. Sleepers of "jarrah" and sugar-gum treated with a liquid called "Carbolineum Avenarius" resisted the attack of white ants for two months, while untreated sleepers were badly eaten, but the preservative effect diminished after the lapse of a few more months. The same result was obtained with another compound termed "Anti-Termite." In general the attack of both white ants and teredo is more severe in tropical than in sub-tropical or temperate regions.

The only native timber brought under the author's notice that is really suitable for buildings and public works in the northern territory of Australia is the cypress-pine which resists the attacks of the teredo and white ant, though the latter will strip the sapwood from it. It will not, however, stand heavy shocks or severe transverse strains.

(For the preservative effect of wood creosote against the ravages of the teredo see this Journal, 1890, 1005).

—B. B.

On the Action of Magnesium Sulphate Solutions on Cement. Michaelis. *Thonind. Zeit.* **15**, 18.

IN a discussion on comprehensive methods of testing materials for building purposes, the author stated that the magnesia had no specific action in the experiments with magnesium sulphate, and that the sulphuric acid only is a factor in the decomposing action exerted on hydraulic limes or cements by solutions of sulphates. The magnesia simply separates out as hydrate, and is visible as a slimy substance. The author agrees with an opinion of F. Schott concerning his investigation of Scott's cement, that disintegration was due to the formation of a calcium sulphate containing more than two, and probably as many as seven, equivalents of water.—G. H. B.

Wearing Properties of Cement for Paving Purposes. Gary. *Thonind. Zeit.* **15**, 233—235.

THE process for ascertaining the wear-resisting qualities of cement to be used in the preparation of paving stones and similar articles subject to attrition, adopted by the Imperial testing works for building materials, consists in pressing the substance to be tested on a cast-iron disc revolving at the rate of 22 revolutions per minute, and fed with emery, the loss of weight of the test-piece after a standard number of revolutions being ascertained. In the case of cement, cubes, the sides of which had an area of 50 sq. cm., were made by the Böhme hammer apparatus, hardened in air or water for 7 or 28 days, and subjected to the test outlined above.

The following table shows the character of some cements tested:—

Specific Gravity after Ignition.	Time of Setting.	Fineness: Per Cent. Residue on a Sieve of		Tensile Strength: Kilos. per Square Centimetre.		
		500 Meshes per Sq. Cm.	100 Meshes per Sq. Cm.	7 Days.	28 Days.	
	Hours.					
1	3'125	1	26	2'5	{ Neat 32'25 { 1:3 13'60	37'23 20'90
2	3'125	5	22	3'0	{ Neat 44'88 { 1:3 18'38	52'90 23'80
3	3'107	3	4	0	{ Neat 48'93 { 1:3 19'80	55'15 25'03
4	..	11	6	0'1	{ Neat 25'00 { 1:3 19'78	27'73 28'05
5	2'778	7	6	0'5	{ Neat 27'83 { 1:3 17'18	38'83 30'03
6	3'145	3	11	2'7	{ Neat 48'90 { 1:3 20'68	50'73 32'58

Samples 4 and 5 are puzzolana cements.

The behaviour of these cements alone and mixed with various quantities of sand, hardened in air and water, is shown in the following table:—

No.	Age.	Kept in Moist Air.				Kept under Water.					
		Neat.	1:1.	1:2	1:3	1:4	Neat.	1:1	1:2	1:3	1:4
1	7 days	5'5	4'2	3'5	0'1	8'9	5'0	3'7	3'8	7'9	10'4
	28 days	7'9	4'5	1'9	9'7	13'8	2'9	1'8	2'7	4'1	6'8
2	7 days	4'6	2'5	3'4	8'3	9'5	4'6	1'7	3'0	6'5	8'8
	28 days	3'9	2'9	3'5	6'0	7'3	3'6	1'8	2'3	5'0	5'6
3	7 days	5'4	2'9	6'1	18'3	62'8	2'4	2'1	2'1	4'7	15'0

—B. B.

PATENTS.

Improvements in and Means for the Manufacture of Cement. W. R. Taylor, Rochester, Eng. Pat. 5719, April 15, 1890. 8d.

In the usual processes the cement materials are made into cakes by mixing with water, and are then placed in the kiln with solid fuel. According to this invention the blocks of cement material are made up by mixing with a liquid fuel, as petroleum residue or the like. These blocks are made perforated or corrugated, so as to expose a large surface for heating. The coke in the kiln is sprinkled with liquid fuel. The kiln is fed from above with blocks made as above

The results are given in cubic centimetres ground away, the loss of weight being translated into the corresponding volume.

The test-pieces whose behaviour is recorded in the columns headed "Kept under water" were kept in air for 24 hours after gauging, remained the rest of the time in water, and were removed therefrom one hour before being tested.

A study of this table reveals that the superiority in point of endurance of the older test-pieces was not great, and in some cases the order of merit was reversed. This is probably due to the cement having become somewhat brittle in the long as compared with the short time test. The same influence is at work in the case of the test-pieces kept in air, the loss by attrition being generally greater than when they were placed under water.

The important fact that neat cement wears away faster than fairly rich mixtures of cement and sand is also clearly shown. The reason for this is tolerably plain: When neat cement is subjected to attrition, the face is ground away evenly, and fresh particles are continually exposed and removed. In the case of mixtures of cement and sand, the cement lying between the grains of sand is removed, and the harder sand takes most of the wear as long as the cement in which it is partly embedded resists the shearing stress produced by the grinding process. That this is what really goes on is shown by the sudden increase in quantity worn away when the proportion of sand exceeds a certain limit; the cement no longer suffices to hold the sand together, and the removal of large amounts is easy.

The large differences in the adhesive powers of various cements is shown by the corresponding fluctuations in the table. The best results are given by mixtures of one part of cement to two or three of normal sand, the increase in loss by wear rising rapidly when this proportion is exceeded. Other things being equal, the quantity of sand that may be added without causing a serious rise in rate of wear increases with the fineness of the cement.

and with fuel, and the clinker withdrawn from the bottom, so that the process is continuous. One form of furnace described is an inclined rotating furnace, in which the materials travel gradually to the lower end, from which they are removed.—V. C.

Improvements relating to the Treatment of Gypsum for Building, Statuary, and other Purposes. G. F. Redfern, London. From W. Heller, Berlin, Germany. Eng. Pat. 16,553, October 17, 1890. 6d.

The object of this invention is to obtain from gypsum materials similar in appearance to natural marbles, but which resist better the action of the weather. The process

of burning with alum is ineffective, and borax has likewise been found to be unsuitable. The borate of *potassium*, however, effects the desired result, forming an insoluble crystalline compound with gypsum burnt so as not to contain more than 10 per cent. to 2 per cent. of its original water of crystallisation. The gypsum used must not contain carbonate of lime, nor must it be of the fibrous kind. After dipping in the solution of borate of potassium, the blocks are heated to 80° C. or 100 C. and then dipped in the solution of such metallic salt as will impart the desired colour. To increase the resistance to the action of the weather the material is heated to 80° C. and dipped while still hot in ozokerite or some similar liquid.—V. C.

X.—METALLURGY.

A Study in Thermo-Chemistry; the Reduction of Metals from their Ores. W. N. Hartley. *Scient. Proc. Roy. Dublin Soc.* 1891, 7, 35—42.

AFTER explaining the terms used in the paper (in which "a gramme atom is an atomic weight in grammes," and "a heat-unit is the quantity of heat required to raise 1 kilogramme of water 1° C."), and defining an *exothermic* reaction, in which heat is evolved, and an *endothermic* reaction, in which heat is absorbed, giving an example of each reaction, the author treats of the—

Conditions of Chemical Change in Smelting Operations.—All chemical reactions take place only within certain limits of temperature; at low temperatures chemical combination generally cannot take place, while at very high temperatures chemical combinations cannot exist.

The ores of the useful metals are for the most part oxides, carbonates or sulphides; the two latter are generally converted into oxides by roasting.

In the smelting operations, either in the blast or reverberatory furnace, the following functions are performed:—(a.) Initiation of the reducing process by raising the ore to a suitable temperature. (b.) Reduction of the ore by carbon monoxide. (c.) In certain cases, in which the reducing process consists of feebly exothermic reactions, maintaining the reducing process by supply of extraneous heat.

Reduction is considered under the following heads:—(1.) Reduction by means of furnace gases. (2.) Reduction by carbon. (3.) Reduction by another metal. (4.) "Reduction by air." In the furnace the fuel is first burnt to carbon dioxide; this, as is well known, in contact with more red-hot fuel becoming converted into carbon monoxide. The furnace gases consist chiefly of carbon monoxide and some hydrogen. The difference in the heat evolved by the combustion of various substances is considerable, as shown in the following equations:—

- (1.) $\text{H}_2 + \text{O} = \text{H}_2\text{O gasous} + 58\cdot2 \text{ heat-units.}$
- (2.) $\text{C} + \text{O} = \text{CO gasous} + 28 \text{ heat-units.}$
- (3.) $\text{CO} + \text{O} = \text{CO}_2 \text{ gasous} + 69 \text{ heat-units.}$
- (4.) $\text{C} + \text{O}_2 = \text{CO}_2 \text{ gasous} + 97 \text{ heat-units.}$

The reducing action of carbon monoxide will be seen from equations (1) and (3) to be stronger than that of hydrogen by 10·8 heat-units, as the former evolves 69 heat-units for every atom of oxygen removed from an oxide, while the latter evolves 58·2 heat-units. "Consequently it is necessary to consider the action of carbon monoxide and of carbon in smelting processes, but not that of hydrogen."

All those metallic oxides the heat of formation of which is less than 69 heat-units are capable of reduction in a reverberatory furnace.

Thermo-Chemical Equations.

(1.) REDUCTION ACCOMPLISHED BY MEANS OF FURNACE GASES.

Smelting of Lead Ores; Reduction of Lead Oxide:—

Reduction of Copper Oxide:—

Reduction of Ferroso-ferrie Oxide:—

The process of reducing ferroso-ferrie oxide in the smelting of iron probably takes place in the two stages—

and

but exact thermal data concerning these reactions are wanting.

Smelting of Tin Ores; Reduction of Stannic Oxide:—

These being all exothermic reactions, for the most part are easily brought about, but the last evolves little heat "and so requires the highest temperature to be applied in order to begin the reaction."

(2.) REDUCTION BY CARBON.

Zinc Smelting.—In the smelting of zinc, the ore, usually calamine, is mixed with powdered anthracite and strongly heated in fireclay retorts: the carbonate is first converted into oxide and this is reduced. The reaction may be stated as follows:—

"Here it will be seen that the reaction is strongly endothermic, and it probably does not take place in the zinc smelting furnace. It necessitates a very high temperature in order that 58·2 heat-units may be supplied to each molecule of zinc oxide and charcoal. It is, however, much more probable that the CO_2 driven off the calamine became CO by the action of excess of carbon, and the reaction is then as follows:—

But

The result as to heat disturbance is therefore the same, viz., absorption of 58·2 units."

(3.) REDUCTION BY ANOTHER METAL.

Certain ores are capable of reduction by being heated in contact with another metal more easily obtainable or less costly than that to be extracted. The following are examples:—

Lead Smelting:—

Reduction of Mercury Ores:—

Special Action of Sodium.—"Magnesium and aluminium are incapable of reduction from their oxides, and are therefore converted into chlorides from which compounds they may be separated by the action of metallic sodium when the material is heated sufficiently to initiate the reaction." (See this Journal, 1890, 737—738.)

Reduction of Magnesium from its Chloride:—*Reduction of Aluminium from its Chloride:—*

(4.) AIR-REDUCTION PROCESS.

In combining with sulphur, metals evolve less heat than in uniting with oxygen, therefore it will be seen that oxygen can decompose sulphides yielding an oxide. If the oxide be only feebly exothermic the metal will be produced by the action of heated air upon the sulphide thus:—

Reduction of Mercury from Cinnabar by Air:—

This reaction takes place easily because it is strongly exothermic.

The Smelting of Galena.—A series of four equations is necessary to explain the process:—

(1.) *First Process.*—*The Roasting of Galena to Lead Oxide:—*(2.) *Second Process.*—*The Reduction of Galena by means of Lead Oxide:—*

This reaction being endothermic an amount of extraneous heat must be applied equal to 50.6 units. Hence the necessity for increasing the temperature of the furnace at this stage of the process.

But a third and a fourth change are effective in lead smelting:—

(3.) *The Roasting of Galena to Lead Sulphate:—*(4.) *The Reduction of Galena by Means of Lead Sulphate:—*

This change being very strongly endothermic requires a great increase of temperature.

In conclusion the author draws attention to the value of these figures in clearly defining the various furnace operations and showing the difficulties surrounding the solution of various problems which have led to a waste of time and money on unattainable objects.—O. H.

On Crystallised Ferro-manganese. B. Rathke. Ann. **260**, 326—332.

In examining a number of samples of ferro-manganese containing varying amounts of manganese, the author has observed that those containing the smallest amount show the leafy surface of spiegel iron; in the samples containing about 24 per cent. the crystals are smaller and more like flat prisms; with 41 per cent. they are long flat needles. Compact crystals first appear in the samples containing 72 per cent., and they contain more manganese than the remainder of the sample, i.e., about 76 per cent. Similarly the crystals of the samples containing 82 per cent. contain 82.5 per cent. of manganese. As these crystals appear to be definite chemical combinations, it appeared to the author that the relation of the carbon to the metal in them would throw some light on the condition of the carbon in white iron, which may either consist of a compound of the whole of the iron and carbon or a mixture of a carbide of iron and pure iron.

The crystals were analysed by combustion of the carbon and subsequent determination of the silicon, iron, manganese,

and phosphorus in the usual way. The crystals were found to contain more carbon than the bulk of the sample, and those crystals containing most manganese also contained most carbon. The following are the results of analyses of the crystals:—

C	7.5	7.4	6.47
Si	0.18	0.15	0.52
Fe	9.48	17.0	47.93
Mn	82.45	75.73	44.99
P	0.10	0.12	0.60

Two analyses of bulk samples were:—

C	6.60	6.62
Si	0.09	0.09
Fe	12.00	8.25
Mn	81.24	85.50
P	0.30	0.15

The author hopes to further investigate this subject.

—A. L. S.

The Method of Hunt, Douglas, and Hauch for Extracting Copper. W. Stahl. Berg. u. hüttem. Zeit. 1891, **50**, 13.

Ores containing 4.68—5.88 per cent. of copper, on treatment by the Hunt, Douglas, or Hauch process were only deprived of 2.02—3.86 per cent. The reasons for this bad result are the spongy state of the ore, difficult filtration in consequence of ferric oxide separating out, presence of much manganese (4—6 per cent.), the chloride of which only seems to react with oxides of copper in presence of plenty of oxygen.—A. R.

On the Presence of Native Nickel in the Gravels of a Torrent. A. Sella. Compt. Rend. **112**, 171—173.

On examining auriferous gravels from the Elvo torrent near Piella (Piémont) the author found some metallic grains, soft and strongly magnetic, and resembling grains of native platinum. Hardly more than a decigramme of the substance was collected, and analyses give the following results:—

	Per Cent.
Nickel (containing cobalt)	75.2
Iron	26.6
	101.8

This corresponds nearly to the formula Ni_3Fe . The specific gravity was about 7.8. The particles may have had a meteoric origin.—G. H. R.

PATENTS.

Improvements in Processes for Smelting and Treating Tin Ores, Slags, Slimes, and Furnace Debris containing Tin and other Products, and in Apparatus therefor. A. J. Campion, Margate. Eng. Pat. 2057, February 7, 1890. *8d.*

A furnace is used termed the "Facile" and is similar to an ordinary cupola furnace used for melting cast iron, but is without blower or artificial air-blast. The shaft or body of the furnace may vary in size according to the material to be melted. Above the hearth or well of the furnace, which is provided with a tap hole, six or nine conical holes are made in the sides of the furnace, on a level with the fuel zone, which communicate with the interior. The top of the furnace is closed by a conical cap connected with a hollow flue leading into the chamber of a chimney shaft of considerable interior dimensions, constructed to retain

metallie particles which may be carried over through the flue. The interior of the hollow cap and flue leading to the chamber of the shaft is provided with one or more pipes, through which jets of steam at high pressure are passed. This causes a vacuum and suction draught through the holes above mentioned near the bottom of the furnace sufficient for all the purposes of combustion and smelting.

The charging hole is below the conical cap and hollow flue, and is fitted with an air-tight door, which is only opened when fresh charges of fuel and material have to be added. When slag, slimes, or other furnace debris containing a percentage of from 5 to 22 per cent. of tin combined with silicates and oxides of iron and other metals have to be smelted, these are heated in the furnace with alkali waste, the quantity being twice that of tank waste to the total iron and silica in the slag or debris. The action of this flux is to separate the oxide of iron by its combination with the sulphur in the waste, the lime being free to combine with the silica and alumina, which, together with a small portion of soda in the waste, form a fusible slag. The oxide of tin is liberated, is reduced by the fuel, and finally collects in the well of the furnace. Should the proportion of silica in the slags or debris be very large (exceeding 40 per cent.), the patentee prefers to use a flux of lime slaked with a saturated solution of sodium sulphate or carbonate in the proportion of one of "soda-lime" prepared in this way to one of silica. When the debris is in a fine state of division it is mixed with the flux and pressed into briquettes, dried and smelted. If the metal running from the furnace is hard by reason of the presence of foreign substances, it is fused in a small "Facile" furnace with iron oxide, iron ore, or scale. This removes sulphur. For the removal of tungsten, nickel, cobalt, or other oxidisable metals, it is fused in the same furnace with nitrate of soda or oxide of manganese or both.

If gold, silver, or the platinum group of metals be present, the dross should be smelted in a small "Facile" furnace with litharge or metallie lead in proportion of from one-half to an equal weight of the dross or skimmings containing the precious metals. When it is desirable to separate tin from slags containing tin to form a solder, the slag is melted in any furnace and lead is added, the proportion of the latter being from one-third to one-half by weight of the tin left in the slag.—J. B. C.

Improvements in the Manufacture of Steel or Iron. J. H. Darby, Brymbo. Eng. Pat. 4030, March 14, 1890. 4d.

IN Eng. Pat. 418 of 1888 and Eng. Pat. 20,586 of 1889 (this Journal, 1890, 1134) a process is described by the present patentee whereby molten steel or iron is filtered through a layer of carbonaceous material, the carbon being dissolved or taken up by the metal, the carburised metal being run into a second ladle or cast direct into the moulds. Where the plant does not admit of this process the charcoal, gas carbon, or other carbonaceous matter to be used, is thoroughly dried and a measured quantity introduced by means of a shovel spout or other suitable apparatus into the casting ladle, if possible below the point where the stream of metal flows from the spout of the open-hearth furnace or the Bessemer converter, or the carbon may be enclosed in a case of thin sheet iron or other material and be thrown into the metal, where it will dissolve. The proportions of the carbonaceous matter required will vary with the different grades of metal. The patentee finds that "100 lb. of carbon added to a ladle holding about 10 tons of metal gives excellent results for 5% carbon steel."

—J. B. C.

The Application of Anthracite Gas to Metallurgical and other Furnaces, and Arrangements connected therewith. T. D. Roek, London. Eng. Pat. 6256, April 24, 1890. 8d.

THE object of the invention is to render it possible to apply producer-gas made entirely from anthracite coal to regenerative steel-furnaces and to improve the conditions of application of such gas to metallurgical furnaces in general.

An important feature of the invention consists in providing for the supply of the anthracite gas to a furnace at a fixed, predetermined and carefully ascertained pressure. Gas-holders, pressure gauges, and indicators are used, whereby any required pressure may be maintained. It is necessary also that the supply of air should be carefully regulated, and the author introduces a convenient method for testing the gas with this object.

An arrangement of plant is outlined consisting of producer-gas holder and regenerative furnace. The regenerative furnace may be of ordinary construction, except that suitable means (valve with chain and weighted lever) are provided for the introduction of materials, solid or liquid, for testing the flame. The author tests the flame at the entrance and exit to the furnace. If the testing material, when applied to the entrance of the furnace, is not consumed without smoke, as observed through sight-holes, then more and more air must be admitted with the gas until such testing material is just consumed without producing smoke. If an excessive supply of air is being admitted, then the escaping gases will contain a greater or less amount of unconsumed air, which can readily be detected by the introduction of testing materials at the exit.—J. B. C.

Höpfner's Electrolytic Process for obtaining Copper and Silver direct from their Ores. Dingl. Polyt. J. 279, 162—163.

IN Höpfner's process a bath is used divided by diaphragms into two or more compartments. One division contains the electrolytically insoluble anodes, the second the cathodes of copper plate.

A double salt of cuprous chloride and halogen salt circulates round the anodes and a similar solution passes the cathodes. On the latter metallie copper is deposited at the rate of 2.36 grms. per ampere-hour, that is double the quantity of metal when compared with the use of cupric salt. In case no cuprous chloride were present free chlorine would form at the anode and an electro-motive force of 1.8 volt would be required. The chlorine combines, however, with cuprous chloride to form cupric chloride equivalent to 1 volt. The electrolysis can therefore take place with an E.M.F. of 0.8 volt.

By determining the heat of formation of cuprous and cupric chloride, the author shows that theoretically the electrolysis begins with the consumption of 0.13 volt. The liquid as it flows past the cathodes gradually gives up its copper and is used again. The anode liquors retain their supply of copper. The copper is, however, present as cupric and not cuprous chloride. The latter leaves the bath in a continuous stream. This solution is employed for extracting copper from powdered copper and silver ores in special leaching vessels. Sulphide ores give the following reaction—

The solution of cuprous salt is regenerated, but it is twice as concentrated as previously. To bring it to its normal condition of concentration, it is diluted with the

waste liquors from the cathodes. This regenerated solution may be utilised as before, and the process is therefore a continuous one.

This process is only disturbed by the presence of small quantities of iron, arsenic, antimony, bismuth, &c., which pass into solution in place of copper.

These impurities must not be allowed to deposit with the copper, and the presence of iron materially affects the solvent action of the copper salt on the ore. These impurities can, however, be easily eliminated by precipitation with copper oxide. The silver, if present, is deposited first. The resulting copper is chemically pure. The advantages of the process are that: 1. By electrolysis a solution of cuprous chloride the amount of copper deposited is twice that which would be deposited from a solution of copper sulphate with the same current. 2. The alkaline and earthy alkaline chlorides have such a solvent action on cuprous chloride that solutions free from iron can be employed, which cannot be attained with sulphate. 3. Pure copper may be derived from the most impure ores and from silver ores, silver may be deposited at the same time. With one horse-power 11 kilos. of copper may be deposited in 24 hours. If the work of the necessary pumps and the mechanical agitation of the liquor be included and reckoned at one quarter, and the electro-dynamic power at three-quarters of the total necessary work, with 30 kilos. of coal, 33 kilos. of copper may be obtained, a result never yet reached, and one which permits of the utilisation of the poorest ores.

The process is particularly applicable to the working of copper ores such as are found in Spain and Chili, where fuel is dear.—J. B. C.

Electro-Metallurgy of Aluminium. A. Minet. *Compt. Rend.* **112**, 231—233.

The author has introduced certain alterations into the method previously used by him (this Journal, 1890, 520), for obtaining aluminium by electrolysis. The effect of these improvements has been to diminish the difference of potential required and to increase the yield, so that 32 grms. of metal are now obtained by an expenditure of energy equivalent to one horse-power-hour. (The "horse-power" referred to by the author is the French *cheval-vapeur*, which is less by about 1·3 per cent. than the English horse-power.) The bath used is made up in the same way as before. The vat is a casting of the same form as that previously employed, but its dimensions are smaller and the arrangement of the electrodes is altered. The inside of the vat is lined with a layer of agglomerated carbon, which serves as the *negative* electrode. The aluminium is deposited on this lining, and collects at the bottom of the vessel. The apparatus can be used continuously for a period varying from 20 to 30 days. The following are the details of a day's work with a single vat (one of three arranged in series):—

Density of current (per square centimetre): At the positive pole, 0·75 ampere; at the negative pole 0·5 ampere.

Temperature, 920°.

Duration of the experiment, $t = 22$ hours.

Strength of current, $I = 1,500$ amperes.

Quantity of electricity, $Q/t = 33,000$ ampere-hours.

Theoretical weight, $W = Q/t \times 0·31 = 11,220$ grms.

Weight obtained, $w = 5,500$ grms.

Efficiency of system in terms of $\frac{w}{W} = \frac{w}{Q/t} = 78$ per cent.

Minimum electro-motive force, $e = 2$ volts.

Resistance of the electrolyte, $r = 0·0017$ ohm.

Difference of potential at the electrodes, $E = e + C/r = 4·55$ volts.

Power employed, $P = \frac{QE}{736} = 9·27$ horse-power.

Total expenditure of energy $= P/t = 204$ horse-power-hours.

Weight of metal obtained per horse-power-hour $= 31·2$ grms.

Expenditure of energy per kilogramme of aluminium obtained $= 31·3$ horse-power-hours.

These results are an improvement on those previously obtained, and the manipulations are also simpler.

When commercial alumina is used and transformed directly into aluminium oxyfluoride (without previous

purification) for feeding the bath, the metal obtained contains from 2 to 3 per cent. of impurities, mainly silicon; the proportion of iron is only 0·6 to 0·8 per cent. As usual, the aluminium can be hammered and worked cold. With products free from silicon, the richness of the metal rises to 99 per cent. The author believes that the necessary difference of potential may be further reduced to 4 volts (independently of the current strength). With this difference of potential, the sodium chloride (which forms 65 per cent. of the bath) would no longer be decomposed, for the electro-motive force required for its decomposition is 4·35 volts; consequently the yield (or efficiency) would rise to 70 per cent. The outstanding loss of 30 per cent. appears to be mainly due to the action of the nascent aluminium, which probably attacks the fluoride and forms a sub-fluoride. In fact, the yield increases when the proportion of fluoride in the bath is diminished by dilution. The losses are greatly diminished, and the yield nearly reaches the theoretical amount when the apparatus is used for obtaining alloys of aluminium. In this case the inside lining of the vat is dispensed with. The vat itself is made of one of the metals forming the alloy, and the aluminium in the nascent state unites with it.—D. E. J.

The Atlas Accumulator. *Elect. Rev.* **28**, 207—208, and *Electrician*, **26**, 484.

THE Atlas accumulator is the joint work of C. Hering, Abakanowicz, D'Arsonval, and Picon. In appearance it is somewhat similar to Volta's original pile, the perforated plates being laid horizontally and built up in the form of a tower. The pile of plates is enclosed in a vessel containing the dilute sulphuric acid, so that the mechanical principle of construction may be said to be a compromise between that of the pile and that of the ordinary battery. The plates are of porous lead and of peroxide of lead respectively, the positive being separated from the negative plates by sheets of perforated celluloid or india-rubber. Between and in contact with each pair of positive plates is a sheet of lead which is provided with a kind of *lug* clamped between two screws working on the thread of a rod of antimony-lead alloy which forms the positive pole of the accumulator, and is provided at its upper end with a screw clamp for attaching the wire. The screws on the rod of antimony and lead alloy are free to expand in every direction. Similarly, between each pair of negative plates is a sheet of lead similarly connected with a second rod which forms the negative pole. The chief advantage claimed is specific lightness, so important for traction work. Other advantages are that the plates cannot buckle and that they can readily be examined, and when necessary removed. The following data relating to this accumulator are given:—

Capacity per lb. of plate 9 ampere hours.

Discharging current 7 to 9 amperes per lb. of plate.

Dimensions of a 150-ampere-hour cell $6\frac{1}{2} \times 7\frac{1}{2} \times 13$ inches.

M. Picon holds that accumulators should be charged at a constant potential of 2·3 volts per cell instead of with constant current. By adopting the former plan the charging is done more quickly: thus 3 hours instead of 6½ were taken to charge a Gadot accumulator to within 17 per cent. of maximum. The constant current method also requires towards the end of the operation a higher potential. For charging at constant potential a shunt dynamo is used.

—V. C.

XII.—FATS, OILS, AND SOAP MANUFACTURE.

Researches on Turkey-Red Oil. Scheurer-Kestner. Compt. Rend. **112**, 158—160 and 395—397.

In view of the uncertainty which still attaches to the theories regarding the composition and essential properties of Turkey-red oil, the author gives in these two papers a summary of the conclusions which his work on this subject has led him to adopt. These refer exclusively to the product derived from castor oil by the action of mono-hydrated sulphuric acid. The complex mixture of fatty acids forming Turkey-red oil contains a very large proportion of sulphoricinoleic acid, in which the sulpho group is joined to an atom of oxygen and not to a carbon atom. This is in agreement with the views of Benedikt and Ulzer as opposed to Muller-Jacobs (see this Journal, 1885, 115; 1886, 452; and 1887, 543). The other fatty acids present are regarded by the author, as well as by Juillard, as a mixture of polymerides of ricinoleic acid, but the author differs from Juillard as to the extent of the condensation and objects to that chemist's employment of sodium chloride for salting out the fatty acids on account of the greater polymerising effect of the hydrochloric acid set free. In this respect the use of sodium sulphate is more to be recommended and at the same time the application of heat is to be avoided. Guided by these considerations, the author's researches have led to the following results: Turkey-red oil consists of sulphoricinoleic acid, which is stable at the ordinary temperature, together with mono- and diricinoleic acids, as shown by determinations of the molecular weight by Raoult's method of solution of the substance in acetic acid; the sulphonated fatty acid is hydrated, and in that state is stable; it loses its water completely at 120°, and becomes insoluble by splitting up into sulphuric acid and fatty acid. From a tinctorial point of view, the author notices that it is the sulphonated fatty acid which tends to produce yellow shades of alizarine, whilst the polymerised fatty acids are favourable to the blue shades.

A separation of the acids of Turkey-red oil may be effected by shaking with a mixture of water and ether, when the fatty acids are taken up by the ether and the sulphonated fatty acid is retained by the water, from which it may be separated by salting out with a solution of sodium sulphate. The proportions of the two kinds of acids vary even when produced under apparently identical conditions. The solubility of Turkey-red oil in water is due to the presence of the sulphonated acid, which is therefore the important factor to its solubility. The fluorescence always exhibited by Turkey-red oil is due to the non-sulphonated acids. Polymerisation occurs to a larger extent in the non-sulphonated acids, which gave a molecular weight of 472 as against 402 given by the sulphonated fatty acids obtained in the same experiment. (The molecular weight of the normal acid is 298.) Sulphoricinoleic acid as precipitated from aqueous solution by sodium sulphate forms a syrupy hydrate, and constitutes about 40 to 50 per cent. of the most soluble kind of Turkey-red oil. Its composition approaches that of diriciniosulphonic acid, $(C_{17}H_{32})_2 - CO_2H - CO_2 - O - SO_3, OH$. The two main constituents of Turkey-red oil may be determined volumetrically by the use of litmus and phenolphthalein as indicators successively. Ammonia should be the titrating solution and the volumes of water present should be about the same in all cases in order to obtain comparable results. Litmus becomes blue when the sulphonated acids are neutralised, whilst phenolphthalein is reddened only when all the fatty acids present have been neutralised. Considering the influence of the proportions of the two kinds of fatty acids on the solubility of Turkey-red oil and on the shade obtained with alizarine in the subsequent dyeing, this method of titration may have considerable practical value. A similar product results from the action of sulphuric acid on castor oil or on normal ricinoleic acid.

—G. H. B.

PATENTS.

New or Improved Soft Soap and Method of Manufacturing the same. M. Williams, Liverpool. Eng. Pat. 3503, March 5, 1890. 4d.

To 6 parts of soda soap the patentee adds 8 parts of potash soap, 25—35 parts of water, and 6 parts of ordinary strong solution of silicate of soda or potash, the mixture being thoroughly mixed and boiled. The amount of water to be added depends on the required consistency of the soap. —K. E. M.

An Apparatus for Straining or Filtering Oil used for the Purposes of Lubrication. T. Walton and C. C. Walton, Rochdale. Eng. Pat. 4491, March 22, 1890. 6d.

THE specification relates to the treatment of oil in a hollow vessel of suitable form provided with a number of sieves, the whole being placed in a second vessel provided with outlets for separated oil and water. —K. E. M.

A New and Improved Lanolin Compound and Process for Preparing and Utilising the same, especially applicable to the Preparation of Lubricants. W. P. Thompson, Liverpool. From R. Krause, Wittenberge, Prussia. Eng. Pat. 5229, April 3, 1890. 4d.

THE soap formed by treating wool-grease with alkaline lye is dissolved in water and filtered. To this a solution of alum or other alumina salt is added, whereby a brown precipitate is formed, which is called "aluminium-lanolate." With this substance, when dried, lubricating oils of any viscosity may be produced by dissolving it in any fluid mineral oil. If dissolved in a small quantity of mineral oil a gelatinous substance is obtained which may with advantage be mixed with india-rubber or gutta-percha. Solvents for india-rubber are said to be also solvents for "aluminium-lanolate." In textile industries this substance may also be used as a scouring agent. —K. E. M.

An Improved Manufacture of Soap. C. A. Serre, Leytonstone. Eng. Pat. 7019, May 6, 1890. 4d.

WITH dried soap, preferably olive-oil soap, powdered talc or pumice stone or silica is incorporated. This mixture is re-ground with olive oil containing perfume so that the particles of soap becoming covered with a film of oil lose their tendency to clog under the influence of atmospheric moisture. —K. E. M.

Process and Apparatus for Smelting Margarine, Tallow, or other Crude Fatty Substances by Means of Hot Air. P. Wild, Berlin, Germany. Eng. Pat. 19,960, December 6, 1890. 11d.

THIS invention relates to the rendering of fats by means of hot air and cannot be adequately understood without reference to the numerous drawings accompanying the specification. —K. E. M.

Improvements in the Naphtha Process of Extracting Oils. J. W. Evans, Cleveland, U.S.A. Eng. Pat. 21,196, December 10, 1890. 8d.

THE "naphtha process" of extracting oil from crushed seed is carried out in a percolator. After drawing off the solution of oil in naphtha which separates from the meal by gravity, steam is introduced. This volatilises the naphtha which is drawn off at the top of the percolator. In order to facilitate the volatilisation of the naphtha, and at the same time to remove the residual oil, the presence of which is objectionable in the meal when used for cattle food, the inventor introduces steam in several places into the

percolator and draws off the naphtha vapours from the top and bottom; the vapours escaping at the bottom carrying with them the residuum of oil.—K. E. M.

An Improved Filter for Oil and other Liquids. C. A. Koellner, Neumühlen, Germany. Eng. Pat. 474, January 10, 1891. 6d.

THE patentee claims the use of filtering apparatus in which the liquid to be filtered passes through filter-beds sideways or upwards and then downwards; also an arrangement by which the filtering process may be observed from outside, and the porosity of the filtering material regulated.—K. E. M.

XIII.—PAINTS, PIGMENTS, VARNISHES, AND RESINS.

PATENTS.

Improvements in the Process of and Apparatus for Producing Ferro-ferric and Ferric Oxides. A. Crossley, Pontypool, and J. W. Jones, Manchester. Eng. Pat. 8914, June 9, 1890. 8d.

THE salts of iron, &c., are heated in retorts of special construction, fully described and illustrated in the specification, and hot or cold air, or steam, is drawn over the surface of the powder by exhausting apparatus of any suitable kind.—E. G. C.

Improvements in the Manufacture of Paints. W. A. Hall, Bellows Falls, U.S.A. Eng. Pat. 16,786, October 21, 1890. 4d.

THIS invention relates to the manufacture of what are termed "water-paints," the material, which contains no oil, and does not scale off or crack, being composed of "hydrous silicate of magnesia," dextrin, gypsum, carbonate of calcium, powdered alum, and salt.—E. G. C.

Improvement in the Preparation of Gold Paint for Use in Gilding and the Like for Internal Decorations. John James, and R. W. Tennant, Aberdeen. Eng. Pat. 17,988, November 8, 1890. 4d.

"Pur gutta-percha steeped in benzol for 24 hours, then pressed and strained, after 24 hours again strained, then allowed to stand for 14 days. On the expiry of the 14 days the top half to be taken off and the remaining half allowed to settle for 16 hours, and both upper halves mixed together. After this benzoline added and strained a third time, then add gold bronze and mix all together."—E. G. C.

XIV.—TANNING, LEATHER, GLUE, AND SIZE.

On the Oxidation of Tanning Materials. R. Jahoda, Zeits. f. angew. Chem. 1891, 104—105.

MANY tanning materials absorb oxygen when exposed to the air in a moist condition. The author has tested the above fact on some of the more common tanning materials, and has compared the results obtained by Lowenthal's and the gravimetric methods before and after exposure to the air. The former method, which depends on oxidation, is most affected by this change. Pine bark by this method showed a falling off of from 6.65 to 2.29 per cent. of the available tannin, whilst the same bark showed by the gravimetric method a decrease of from 9.27 to 6.4 per cent. This decrease seems limited in extent, as while it continued for 14 days it did not further decrease when

exposed for 30 days. In the above example the final point seems to be 2.29, and by the gravimetric method 6.59. This decrease in the percentage is proportional to the length of time of exposure to oxidation.

Oak bark and quebracho wood showed no change. Oak wood showed a slight decrease. The tanning material was moistened with water in a flask and oxygen passed in from time to time, the flask being corked up and allowed to stand. The change is without doubt due to oxidation of the tannin, water assisting the action by parting with dissolved oxygen, and at the same time dissolving the tannin and rendering it more oxidisable.

The author appends a table of some dozen results as the result of oxidation from 5 to 30 days.—D. A. S.

PATENTS.

The Preparation of Skins, Kips, and Hides, by an Improvement in the Process known as "Unhairing" or "Pulling." F. R. Maggs, Yeovil. Eng. Pat. 7509, May 14, 1890. 4d.

THIS invention consists in the application of crude sulphide of barium, containing soluble sulphides, mixed with slaked lime to the unhairing of hides, kips and skins. The hides or skins are brushed with the mixture made into a paste with water. The "strength" of the mixture is entirely dependent on the nature and condition of the skins, kips, or hides under treatment. For ordinary skins it would require about 10 lb. of the barium sulphide to 40 lb. of the slaked lime.—B. H.

Improvements in Tanning. J. E. Pujos, Paris, France. Eng. Pat. 11,397, July 21, 1890. 6d.

THIS invention is for a quick method of tanning. The hides are first soaked and limed in the usual way and are then unhaired, fleshed and "scudled." They are next immersed in a dilute solution of oxalic acid containing 10—15 grms. of oxalic acid to each hide. The hides are then removed from the bath and worked on both sides, after which they are thoroughly washed till almost quite free from acidity. They are now sent into tan-liquor consisting of what the inventor calls "converted tannin." This tanning liquor is prepared as follows: To 100 kilos. of extract (oak or chestnut, &c.) of 25 are added 100 litres of clear water. 15 kilos. of commercial ammonia are then added and the mixture thoroughly agitated; 8 kilos. of ordinary commercial sulphuric acid are next added and stirring continued till complete mixing has taken place. The hides or skins prepared as above are treated first with liquors of "converted tannin" of the lowest strength and gradually brought into stronger liquors, till they are finally operated on with the strongest liquors of 4—5° B. "It may also be stated that this process of converting tannin by means of ammonia and sulphuric acid is suitable for all tanning substances, such, for examples, as oak, chestnut, sumach, scarlet oak, yallonia casalpina coriaria, the mangrove or mangle, &c."—B. H.

Improvements in Machinery or Apparatus for Fleshing, Shaving, Grounding, and otherwise Treating or Finishing Hides or Skins. W. R. Pullman and H. Smith, Godalming. Eng. Pat. 131, January 3, 1891. 1s. 1d.

THIS invention relates to improvements in machinery for performing upon green or manufactured or partly manufactured hides or skins, operations for the finishing of the same, such as grounding, paring, fleshing, shaving, frizzling, reducing, staking and levelling. The specification is unsuitable for abstraction, and would be unintelligible without the accompanying drawings.—B. H.

XVI.—SUGAR, STARCH, GUM, Etc.

On Wood-sugar (Xylose) and Wood Gum (Xylan).
E. W. Allen and B. Tollens. *Annalen*, **260**, 289—306.

Many vegetable substances when warmed with a hydrochloric acid solution of phloroglucinol yield a cherry-red colouration, and when distilled with dilute acids yield an estimable quantity of furfural. These two reactions are characteristic of the pentaglucooses and those bodies which yield these sugars on hydrolysis.

Wood and other similar bodies when moistened with phloroglucinol in the cold yield the red *lignin* reaction. The object of this research was to obtain more detailed knowledge concerning the bodies which yield the above pentaglucoose reaction.

Xylan and Xylose from Straw.—Straw is treated with 2 per cent. ammonia and well washed; it is then soaked in 4—5 per cent. soda for two days, and the alkaline liquor separated; from this strong alcohol precipitates a gum. The gum is washed with alcohol acidified with hydrochloric acid until all the soda is removed, the alcohol removed by ether and the gum dried over sulphuric acid. Further similar treatments of the straw residue yield more gum. The total yield is 16.2 per cent. of the straw. The gum gives the pentaglucoose reaction on warming with phloroglucinol and hydrochloric acid, but does not give the lignin reaction. No indication was obtained of bodies yielding other sugars on hydrolysis. The gum contained 28.3 per cent. of ash, which consisted chiefly of silica.

By distillation with hydrochloric acid the gum yielded 11.0—19.2 per cent. furfural. A solution of the gum in soda was levo-rotatory $[\alpha]_D = -84.1$. When hydrolysed with 5 per cent. sulphuric acid, the gum yielded 7.4 per cent. crystallised xylose.

Xylose from Cherrywood.—Although cherry-tree gum yields arabinose on hydrolysis yet the wood of the same tree when treated as above yielded a gum which when hydrolysed produced xylose. Shavings of the wood give the pentaglucoose reactions; when distilled with hydrochloric acid the yield of furfural is 4.8 per cent. The wood yielded 12.4 per cent. of gum and 87.5 grms. of gum yield 19.4 grms. of xylose.

Gum and Pentaglucoose from Loofah.—Loofah consists of the isolated vascular bundles of the fruit of *Luffa cylindrica*. It gives both the lignin and pentaglucoose reactions. On treating loofah as above 5.7 per cent. of a gum was obtained. The gum gives the pentaglucoose reaction, but no reaction with iodine indicating starch or cellulose. When distilled with hydrochloric acid it yields 25.8 per cent. furfural. Dissolved in soda it is levo-rotatory $[\alpha]_D = -69.2$.

Arabinose from Beetroots.—A gum stated to be identical with arabic acid has been extracted from beetroots by milk of lime. Washed beetroot slices give a slight red colouration on moistening with a hydrochloric acid solution of phloroglucinol. When treated with soda as above 10.5 per cent. of a gum was obtained containing 14.6 per cent. of ash. This yielded arabinose on hydrolysis.

On Wood Gum (Xylan) and the Lignin Reaction.—The lignin reaction has been used to indicate the presence of xylose- or arabinose-yielding bodies, and has been trustworthy. The authors have observed that the reaction is diminished after extracting straw, &c. with soda as above, and after repeated extractions disappears. The extracted wood gum does not, however, yield this reaction, it may be that the body giving this reaction and extracted by soda is soluble in alcohol, and is not precipitated with the wood gum. The red colouration produced by heating phloroglucinol and hydrochloric acid when examined in the spectroscope shows a band in the green between D and E, whilst the red colouration produced in the cold (lignin reaction) shows no such band. It thus appears that the two reactions have no connexion.—A. L. S.

On Xylonic Acid. E. W. Allen and B. Tollens. *Annalen*, **260**, 306—313.

Six grms. of xylose dissolved in 30 grms. of water were oxidised by 12 grms. of bromine at the ordinary temperature for 36 hours. The excess of bromine was removed by heating the solution and the hydrobromic acid by silver and lead carbonate, the excess of these metals being removed by sulphuretted hydrogen. The filtrate was neutralised with calcium carbonate, and as it did not crystallise the lime salt was precipitated by alcohol. It contained 10.2 per cent. of calcium, calcium xylonate, $(C_5H_9O_6)_2Ca$, contains 10.8 per cent. of calcium. The authors have not been able to crystallise this salt, nor have they had more success with the zinc or silver salt. They have, however, crystallised strontium xylonate. The air-dried salt has a composition $(C_5H_9O_6)_2Sr \cdot 8\frac{1}{2} H_2O$; on long exposure to the air it loses 2½ molecules of water and then contains 6 H₂O.

Xylonic acid and its salts possess very different properties to arabinonic acid and its salts, as the calcium salt of the latter crystallises easily, and strontium arabinonate crystallises with 5 H₂O. Strontium xylonate is dextro-rotatory $[\alpha]_D = +12.14$.

Xylonic acid has not been crystallised; the acid as obtained by adding the calculated quantity of hydrochloric acid to strontium xylonate is first levo-rotatory, but this soon changes to dextro-rotation, the constant value being $[\alpha]_D = +17.48$. Strontium arabinonate is dextro-rotatory $[\alpha]_D = +1.96$; arabinonic acid prepared from the strontium salt by adding the calculated quantity of hydrochloric acid is levo-rotatory, the levo-rotation gradually increasing to the constant value $[\alpha]_D = -45.86$. It is thus evident that xylonic acid and arabinonic acid are not identical but isomeric.—A. L. S.

Levosin, a New Procimate Constituent of Cereals.

C. Tanret. *Compt. Rend.* **112**, 293—295.

WHEAT, rye, and barley contain a well defined substance which is levo-rotatory and to which therefore the name of *levosin* has been given. To isolate this new body the ground grain is extracted with 50 per cent. alcohol, and the extract treated with two volumes of 94 per cent. alcohol, whereby a quantity of gum is precipitated. This is filtered off, the alcohol distilled off from the filtrate and the residue treated with baryta water until a precipitate forms, which redissolves at once. The solution is filtered and the filtrate boiled with a large excess of baryta water, when a precipitate is formed which is filtered, washed with baryta water and decomposed by carbon dioxide. The resulting solution, after filtering off the barium carbonate, contains the levosin, which remains behind on evaporation still contaminated however, with 0.5—1 per cent. of barium salt, which can be removed by dissolving the above residue in 60 per cent. alcohol, and separating the barium by addition of the requisite quantity of sulphuric acid. The barium sulphate is then filtered off, the levosin precipitated by the addition of 95 per cent. alcohol, taken up with water and the aqueous solution evaporated. Levosin is a white amorphous solid, soluble in water in all proportions, very soluble in dilute, but almost insoluble in strong alcohol. It melts together at 145 C., but is only completely melted towards 160 C. Its specific gravity is 1.62, and its rotatory power, which is unaffected by temperature, $[\alpha]_D = -36$. An analysis of the product dried at 110 C. points to the empirical formula $C_{12}H_{20}O_{10}$; a molecular weight determination by Raoult's method to the molecular formula $C_{18}H_{30}O_{16}$. Exposed to the air the dry substance takes up 4 molecules of water to form the hydrate $C_{18}H_{30}O_{16} \cdot 4 H_2O$. Levosin does not reduce Fehling's solution, nor does it undergo fermentation either with yeast or with diastase. The hydrate is very readily hydrolysed by dilute acids, and even by heating with water to 100° in a sealed tube for 24 hours. The resulting solution has a rotatory power $[\alpha]_D = -76$, and contains about 75 per cent. of levulose, the remainder being a feebly dextro-rotatory glucose.

Levosin is not attacked by solutions of the alkaline hydrates; it forms compounds with bases, some of which have been analysed. The barium compound, $C_{18}H_{26}Ba_4O_{20}$,

is formed by the addition of baryta water to a solution of levosin. It is insoluble in an excess of baryta water, and is dissociated by water into the compound $C_{18}H_{15}Ba_2O_{10}$, which is only slightly soluble. In presence of sugars, however, this barium salt redissolves, until the former are completely saturated, a fact which is made use of in the method given for the isolation of levosin. A calcium salt, $C_{18}H_{15}Ca_2O_{10}$, and two lead salts, $C_{18}H_{15}Pb_2O_{10}$ and $C_{18}H_{15}Pb_3O_{10}$, are described. Lead acetate precipitates the former of these lead salts only after addition of alcohol; the latter is insoluble in water and results when levosin is treated with an ammoniacal solution of lead acetate.

Levosin yields both a tri-acetyl and a tetra-acetyl compound. With nitric acid a slightly explosive ester results in the cold. On further action oxalic acid is formed without the intermediate production of mucic acid.

Levosin has been found in rye, wheat, and barley to an extent varying from 0.3 to 2.0 per cent. on the dry material. Barley contains the most, and the quantity is greatest when the cereal is matured. When dried, wheat and barley only contain 0.1—0.2 per cent. of levosin. None was detected either in oats or in dried maize.—C. A. K.

The Conversion of Starch into Dextrin by the Butyric Ferment. A. Villiers. *Compt. Rend.* **112**, 435—437.

THE conversion of starch into dextrin is easily effected as follows:—50 grms. of potato starch and 1,000 cc. of water (not distilled) are made into a paste. The paste, contained in a flask which it must nearly fill, is inoculated at 100° C. with a few cubic centimetres of a cultivation of *Bacillus amylobacter*. The flask is closed with a plug of sterilised cotton and placed in an oven kept at 40° C. In 24 hours the starch paste will generally have become liquid, but the fermentation is allowed to proceed until a drop of the liquid no longer gives a blue or violet colouration with iodine. This result is attained in 2—4 or more days, according to circumstances. The *bacillus* cells, which at the beginning of the experiment form straight mobile rods, become towards the end of the fermentation thickened at one end and assume a tadpole-like shape. A little gas is liberated during the fermentation, but its quantity is insignificant. The liquid finally obtained smells of butyric acid, of which about 0.3 part is produced per 100 parts of starch taken. The chief product, however, is dextrin, which may be separated by filtration, evaporation, and precipitation with alcohol. The dextrin forms when dry a white, friable, very hygroscopic mass, which possesses a slightly sweet taste and consists of a mixture of different dextrins, which vary in specific rotatory and reducing powers. Iodine colours the dextrins having a high rotatory power reddish, whilst the others are not coloured. The reducing powers of these dextrins vary inversely as their rotatory powers, as the following table shows:—

Specific Rotatory Power.	Reducing Power.
	K.
156	28.9
175.4	11.3
207.5	5.0

It remains to be decided whether these dextrins are identical with those produced by the action of acids or diastase on starch. It is remarkable that the dextrins formed are not accompanied by maltose or glucose. This fact seems to show that the conversion of the starch is brought about without the aid of any diastase secreted by the butyric ferment; for in such case, reasoning by analogy, the further reduction of a portion of the dextrin to maltose might fairly be expected.—H. T. P.

XVII.—BREWING, WINES, SPIRITS, Etc.

On the Improvement of Inferior Brewing Water by Sand Filtration. W. Schultz. *Allgem. Zeits. f. Bierbr. u. Malzfabr.* 1891, **19**, 1.

See under XVIII. B., page 477.

Diastase. J. Szilágyi. *Chem. Zeit.* **15**, 349—351.

DIASTASE was prepared from barley and oat malts by digesting the green malt with alcohol of 20 per cent. strength. To the solution obtained alcohol was added until a flocculent precipitate began to form. After settling, the clear liquid was treated with a double bulk of alcohol, the diastase thus precipitated being filtered off, washed with alcohol and ether and dried over sulphuric acid.

Diastase thus prepared obstinately retains a considerable percentage of ash, which may be removed by repeated dialysis. An elementary analysis of the diastase obtained yielded the following results calculated on the ash-free substance:—

	Barley Malt Diastase.	Oat Malt Diastase.
Carbon	46.80	48.12
Hydrogen	7.44	7.04
Nitrogen	9.98	10.04
Sulphur	1.14	1.19
Oxygen	31.64	33.61
	100.00	100.00

In order to test the saccharifying power of barley-malt diastase, varying amounts of a solution containing 0.1 gm. of diastase per 500 cc. were added to lots of 20 cc. of a solution of soluble starch prepared according to Lintner's directions. 100 cc. of starch solution were equivalent to 2 grms. of air-dried starch. The mixtures were allowed to stand for one hour at the ordinary temperature. The maltose formed was then determined, the results obtained being as follows:—

Diastase used.	Diastase used.	Maltose formed.	Corresponding Amount of Starch.	Corresponding Amount of Air-dried Starch (containing 13.4 per Cent. of Water).	Percentage of Starch converted into Maltose.
Cc.	Grms.	Grm.	Grm.	Grm.	
5	1	0.1228	0.1229	0.1419	35.48
10	2	0.15079	0.1428	0.1648	41.20
15	3	0.18484	0.1722	0.1988	49.72
20	4	0.20739	0.1964	0.2256	56.40
25	5	0.2220	0.2103	0.2428	60.75
30	6	0.2275	0.2155	0.2488	62.20

Similar experiments were made at more elevated temperatures, the time of action being reduced to 30 minutes. The results are given in the table on next page:—

Diastase used.	Saccharifying Temperature in °C.	Maltose formed.	Percentage of Starch Converted into Maltose.
Mgms.		Grm.	
1	40	0.15630	42.7
	50	0.18880	51.6
	60	0.15876	43.4
2	40	0.21840	59.7
	50	0.25900	68.3
	60	0.21910	59.9
3	40	0.2458	67.2
	50	0.2878	78.7
4	40	0.2652	72.5
	50	0.2872	78.8

Oat-malt diastase was examined in the same way as above, the results obtained being as follows:—

Diastase used.	Saccharifying Temperature in °C.	Maltose formed.	Percentage of Starch converted into Maltose.
Mgms.		Grm.	
1	40	0.1770	48.37
	50	0.21238	58.00
	60	0.1770	48.37
2	40	0.2418	66.10
	50	0.26546	72.54
	60	0.24780	67.74
3	40	0.28318	77.37
	50	0.29491	80.60
	60	0.2890	77.55

From these numbers it appears that oat-malt diastase has a slightly stronger fermentative action than that from barley-malt; and this is practically confirmed by the fact that the use of oat-malt for saccharifying purposes in distilleries leads to a better and more complete fermentation of the wash than is the case when barley-malt is employed, other circumstances being equal.—H. T. P.

The State of Combination of Sulphuric Acid in Plastered Wines, and the Detection of Free Sulphuric Acid.

L. Magnier de la Source. *Compt. Rend.* **112**, 341—343.

THE author is of opinion that *fully* plastered wines always contain potassium bisulphate. Such a wine contains no potash in excess of that required to form neutral potassium sulphate with the sulphuric acid. A wine contains as much tartaric acid after as before plastering with pure plaster. If at any time it deposits tartar, it does so at the expense of the potassium of the potassium sulphate, and consequently a corresponding amount of potassium bisulphate is formed. Completely plastered wines are rare in commerce, yet it is often found in analysing plastered wines that very little difference exists between the total ash and the potassium sulphate. In such wines free sulphuric acid can generally be detected. A pure unplastered wine containing naturally 0.32 gm. of sulphuric acid (H_2SO_4) per litre was treated with the following quantities of sulphuric acid:—

—	Per Litre.	—
	Grms.	
a	4.00	Undrinkable.
b	1.80	Undrinkable.
c	1.00	Very acid, but good.
d	0.55	Most agreeable flavour.

Each of these mixtures was divided into two equal parts, one part being saturated with potassium carbonate. The eight lots were then evaporated to dryness and incinerated, the sulphuric acid being determined in the residues. The following results were obtained:—

—	Wine + Sulphuric Acid.	Wine + Sulphuric Acid + Potassium Carbonate.
	Grms. per Litre.	Grms. per Litre.
a	1.19	4.01
b	1.21	2.00
c	1.20	1.30
d	0.84	0.86

These numbers show that the addition of a quantity of sulphuric acid exceeding 1 gm. per litre could not be detected by an analysis of the ash of the wine. Sulphuric acid added in small quantities to unplastered wine ceases to exist in the free state, and no method of analysis would return it as such unless it were again set free by some secondary action. But if this were so, the results would be valueless, because they would apply equally well to plastered and unplastered wines.—H. T. P.

On Italian Wines. E. Niederhäuser. *Pharm. CH.N.F.* **1891**, **12**, 15.

As the consumption of Italian wines has increased considerably the following tables may be of interest:—

For Table see next page.

The commission for wine statistics at Karlsruhe has decided to condemn white wines containing more than .12 per cent. and red wines containing more than .16 per cent. acetic acid. According to these figures the majority of the above Italian wines would be considered bad, which is unjust, as none of them have a taste of acetic acid. The chlorine found in these wines varies considerably, rising as high as 23—25 mgms. in 100 cc.; German wines contain only a few milligrammes.—A. R.

XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, AND DISINFECTANTS.

(A.)—CHEMISTRY OF FOOD.

PATENTS.

A New or Improved Method for Preserving Meat, Fish, and the like. F. Grognet, Paris, France. Eng. Pat. 2620, February 18, 1890. 6d.

FOUR hundred parts of vinegar of “3½ or 4 degrees of strength, 16 parts of kitchen salt, 1 part each of Sumatra or crushed cayenne pepper, green ginger, acetate of potash, and a mixture of the four spices nutmeg, cloves, cinnamon, and laurel” are mixed, allowed to stand for 15 days, and the meat, fish, &c. to be preserved immersed therein. An alternative plan is to paint the perishable articles with the mixture. However prepared, the materials to be preserved are powdered with a mixture of tale and maize flour “preferably of the second quality,” and hung up until sufficiently desiccated. Powdered starch, wood ashes, and other absorptive substances may be substituted, and desiccation aided by causing a current of air to circulate round the objects to be preserved. The constituents and proportions of the first bath may be varied, and its use, though desirable, is not indispensable.

—B. B.

An Improved Process and Apparatus for Preserving Meat and other Alimentary Substances. G. Dosmond and P. Rozes, Paris, France. Eng. Pat. 3995, March 14, 1890. 6d.

CHARCOAL, coal or other suitable carbonaceous material is heated in a retort and the gases evolved passed through a refrigerator into a "clearing chamber" and thence to a gas-holder, whence they are pumped as required into vessels containing the meat or other matter to be preserved. The conservation of perishable foods is said to be complete and the appearance after removal from the preserving chamber unaltered. Vessels filled with the preservative gases can be used for the transport of perishable substances.—B. B.

Improvements in the Manufacture of Ferments, Peptones, and Peptonised Food Products. O. Murray, London. "From The Mosquera Julia Food Co.," Detroit, U.S.A. Eng. Pat. 19,178, November 25, 1890. 4d.

PLANTS of the *Bromeliaceae* family (of which the pine-apple is the best known type), contain, it is said, a ferment whose action upon albumen or albuminoids is analogous to the action of pepsin, and which can digest them in the same manner. Its action upon some albuminoids appears to be even better than that of pepsin. The active substance may be prepared by expressing the juice from pine-apples free from rind, filtering it, and evaporating the filtrate *in vacuo* at a temperature below 45° C. When concentrated it is purified by precipitation with salt or by dialysis, to free it from inert saccharine matter, after which it may be obtained as a paste, powder or "scale-compound."

Other portions of the plant contain the ferment but in less quantity than the juice.

Peptonised foods may be prepared by digesting albuminoids such as are contained in lean meat with pine-apple juice, the proportion being about 4 kilos. of meat (finely chopped) to 450 cc. of juice diluted with an equal bulk of water, at a temperature of 45–50° C. for 3–4 hours, the mass being constantly stirred. The temperature is then raised to 60° C., solution being thereby completed.

Peptones may be prepared from this solution by dilution, filtration and evaporation at a temperature not exceeding 60° C. The product is pure and contains a high percentage of nitrogen, viz., about 11 per cent.—B. B.

Improvements in and relating to Sterilising Apparatus. E. Cohn, Berlin, Germany. Eng. Pat. 20,348, December 13, 1890. 8d.

THE apparatus described is designed so that the bottles or other vessels containing the substance to be sterilised can be closed by mechanical means, either synchronously with the opening of the sterilising oven or at a definite period before or afterwards. According to Koch, "complete sterilisation is only possible when the vessels are closed by streaming vapours," and the object of the patentee is to secure such "streaming" at the time of closing the vessels with sterilised contents.

Various simple mechanical devices for this purpose are figured and described. Generally speaking the mechanism actuating the lid or door of the sterilising chamber is coupled to a bar acting upon the closing-pieces of the bottles. By varying the position of the opening bar or lever relating to that effecting the closure of the bottles, the two operations can take place successively, either being in advance of the other as may be desired or synchronously.—B. B.

Improvements in the Process of and in the Apparatus for Preserving Articles of Food. L. Breglia, Vienna, and F. Breza, Krems, Austria. Eng. Pat. 20,946, December 23, 1890. 6d.

THE process patented consists in preserving perishable articles of food by coating them with a layer of coagulated albumen by exposure to the vapour of glacial acetic acid. The process is conducted in a closed vessel with a perforated false bottom, below which is a layer of felt or

sponge saturated with the acid. The cover being adjusted a valve-cock attached to the cover is allowed to remain open until the vapours of the glacial acetic acid commence to escape through the same. This is certain proof that the air is entirely driven out. The cock is then closed and the materials to be preserved are exposed to the action of the unmixed acid.—B. B.

(B.)—SANITARY CHEMISTRY.

PATENT.

On the Improvement of Inferior Brewing Water by Sand Filtration. W. Schultze. Allgem. Zeits. f. Bierbr. u. Malzfabr. 1891, 19, 1.

A WATER from a cleanly-kept well had a conspicuously bad taste, although it appeared clear as seen in a drinking glass, and a chemical analysis afforded no evidence of substances capable of affecting the taste of the water injuriously. The cause was ultimately found in the presence of a trace of very finely-divided clay which became visible when the water was placed in a long tube, and was removed by slow passage through a sand filter, after which the water acquired a mild normal taste. An examination of 48 waters conducted in the same way showed the presence in all of the same kind of impurity and demonstrated the improvement effected by suitable filtration through sand, and a consequent improvement in the taste of the beer brewed with it. Such filtration was also effectual in reducing the number of germs in a contaminated water from 5,000 bacteria to 8 spores per cc. It is essential that the filtration should be slow, as a rapid filtration can make the water worse by detaching accumulated bacteria from the filtering substance. An arrangement of plant is described for conducting the filtration on a large scale.—G. H. B.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

Contributions to our Knowledge of the Aconite Alkaloids. Part I. On the Crystalline Alkaloid of Aconitum Napellus. W. R. Dunstan and W. H. Ince. Proc. Chem. Soc. 1890–1891, No. 95, 36–38.

THE authors have investigated the properties of a crystalline alkaloid obtained from the root of *Aconitum napellus* by extraction with amyl alcohol, as suggested by the late Mr. John Williams. For a supply of the material they were indebted to the kindness of Messrs. Howards and Sons, of Stratford.

The yellowish indistinct crystals melted at 188.4° (corr.). The original substance appears to have the formula $C_{33}H_{45}NO_{11}$, which is that proposed for aconitine by Wright and Luff (Trans. Chem. Soc. 1879). The alkaloid was purified by repeated crystallisation from a mixture of alcohol and ether, or more readily by conversion into its bromhydride and regeneration of the alkaloid from the salt, or by regeneration from its crystalline aurichloride. It crystallises in tabular prisms belonging to the rhombic system. The crystals are very slightly soluble in water and light petroleum, more soluble in ether and alcohol, most soluble in benzene and chloroform. They melt at 188.5° (corr.). Contrary to the statements of previous observers, who found aconitine to be levo-rotatory, the authors found an alcoholic solution to be dextro-rotatory $[\alpha]_D + 10.78^\circ$; the aqueous solution of the bromhydride is, however, levo-rotatory, $[\alpha]_D - 30.47^\circ$. On analysis, the alkaloid afforded results which agree best with the formula $C_{33}H_{45}NO_{12}$.

Two crystalline aurichlorides were obtained. One melting at 135.5° (corr.) ($C_{33}H_{45}NO_{12} \cdot HAuCl_4$); the other, a basic aurichloride ($C_{33}H_{45}NO_{12} \cdot AuCl_3$) melting at 129° (corr.).

These compounds are obtained without difficulty, and afford trustworthy means of identifying aconitine. The alkaloid may be readily recovered from them in a pure state.

Aconitine is not appreciably affected by heating at a temperature below its melting point, but at this temperature it is gradually converted into the uncrystallisable base aconine. Prolonged boiling in aqueous solution induces a similar change, but not to the same extent unless an alkali is present. Boiling with water acidulated with hydrochloric acid also produces decomposition of the alkaloid.

Dehydroaconitine or *apo-aconitine* may be readily prepared by heating aconitine with saturated aqueous tartaric acid in closed tubes, as recommended by Wright and Luff. The crystals of this substance melt at 186.5 (corr.). It forms crystalline salts, and in other respects closely resembles the parent alkaloid. The results of analyses agree well with the formula $C_{33}H_{43}NO_{11}$.

An amorphous base was obtained from aconitine, together with benzoic acid, by prolonged heating with water in a closed tube, and appears to be identical with the *aconine* of Wright and Luff. The same substance is formed together with a resinous substance when aconitine is heated with an alkali.

In subsequent discussion Dr. Alder Wright said it was greatly to be regretted that preparations were largely sold under the name of aconitine of which only a very small fraction actually was aconitine, the greater part consisting of relatively inert, other alkaloids. Dr. Thudichum referred to the uncertainty and danger attending the use of "aconitine" owing to absence of uniformity in the products of English, French, and German manufacture. A final determination of the properties and mode of preparing the active principles of the various kinds of aconite would, he said, be a work of great value.

Professor Dunstan said that all the commercial aconitines were more or less impure, chiefly from the presence of amorphous alkaloid, which appeared to be non-toxic. Dr. Waller, of St. Mary's Hospital, intended to fully examine the alkaloids contained in *A. ferox* and *A. saponicum*.

Lavender: Its Cultivation and Distillation. J. C. Sawyer. Chem. and Drug. 1891, 38, 397—400.

The principal lavender plantations are in the districts of Mitcham, Carshalton, and Beddington in Surrey, Hitchin in Hertfordshire, Grove Ferry near Canterbury in Kent, and until recently, at Patcham in Sussex. The Surrey and Hertfordshire plantations are situated on the outcrop of the chalk which surrounds the London basin. The most suitable conditions of soil are found to be light brown loam over chalk—the depth of the loam being very slight, varying from 6 to 18 inches.

The Harvest depends upon the season; white frosts in May retard the growth (especially of plants near overhanging trees), but black frosts do not so injure them. As a general rule the harvest may commence the first week of August if the weather be dry. The cutting usually commences as early as possible in the morning, before the dew is off. Flowers so cut seem to yield more oil than those cut in the heat of the day, but the necessity of getting the whole lot cut quickly, when once ripe and ready, requires cutting to go on all day long, unless many men be employed. In wet weather none should be cut.

The spikes when cut should be kept as much as possible straight together in large bundles and carried near to the stillery, being laid on the ground in the shade in long rows. Some growers allow these heaps to sweat (or partly ferment and partly dry) for some little time before distilling. This is quite a mistake—the oil already exists in purity in the ducts of the flower, and is not an after-product or a "ferment oil," i.e., not an oil produced by after fermentation of the vegetable juices. If the oil as it exists requires oxidation, it is preferable to allow that process to take place after distillation, and not in presence of organic matters which may act injuriously upon it.

The distillatory apparatus may be varied in form according to the amount of work to be done, &c., but the main principle applies in all cases. The body of the still should be very shallow compared with its diameter, otherwise the steam generated at the commencement of the operation, in the lower part of the charge, would condense in its upper part and remain there until volatilised a second time by the rising heat. The less time the oil is subjected to the action of heat the finer its aroma will be.

The basket in which the flower is packed is a copper cylinder, three-fourths the depth of the body of the still; it is perforated at sides and bottom with holes of one-eighth of an inch diameter—to allow free circulation of water. It is provided with a copper lid similarly perforated, and has a lug or ring on each side to allow of its being lifted in and out of the still; this is done by overhead differential pulleys. The Tangye chain pulley can be used, or, for larger work, a swing crane, but several small stills are preferable, for many reasons, to one large one. The sketch shows the still without the pulleys. The copper basket fits within an inch of the still, at sides, and has three or four legs an inch long to rest it on the bottom of the still. The quantity of water put into the still should reach to within one-fifth the height of the basket. The flange at the top of the still is then spread with a lute composed of equal parts of flour and whiting made into a thick paste, and the head, or steam dome, secured by iron screw clamps round the flange. The condenser consists of a coil of tin pipe enclosed in a cylinder or drum of galvanised iron, and this condenser is connected with the still by a curved pipe (also of pure tin) secured at each end by a brass union, the pipe being passed through the connecting screw and ground to a flush surface. The fire is immediately lighted, and the vapours will begin to condense in about three-quarters of an hour from the time

DISTILLATION OF LAVENDER.

of lighting; this is ascertained by feeling the connecting pipe. A copious supply of cold water is then turned into the condenser (which was previously filled); this descends by a piece of zinc pipe to the bottom of the condenser, and the overflow of heated water is carried off at the top into a gutter. The condensed oil and water are collected in a Florence receiver, the oil, of course, floating on the top and the waste water escaping into a waste pipe. The whole of the oil, or the finest part of it, will condense during the first twenty minutes or so of the upper part of the condensing worm becoming hot; this can be verified by watching the receiver and noting the depth which the oil attains on the surface of the water. The last oil which condenses is slightly inferior and it is not advisable to collect it with the first portion. This is managed by substituting another receiver towards the end of the operation. The flow of cold water through the condenser can then be stopped and the furnace door opened to damp the draught. The connecting pipe should be carefully unscrewed with a spanner,

detached, and the clamps removed. The steam dome is then lifted off, and the cylinder with its contents hauled out by the overhead tackle, which hooks on to the lugs by chains. The great weight of this is easily pulled up if differential pulley blocks are used, and, being raised out of the boiling water above the edge of the still, is dragged aside by another rope hooked on to it, and lowered into a barrow or truck. The spent flower is stacked in a heap to rot. The use of the perforated basket is two-fold—first, it enables the operator to pull out the charge clean, all at once, without drawing the fire, so that the still is ready for a fresh charge; second, and most important, it prevents the flower from scorching by contact with any part of the still.

The oil which has collected on the surface of the water in the Florentine receiver is drawn off by a pipette and put into a large bottle to clarify, or deposit watery particles mechanically held in solution. The clear oil is afterwards poured into Winchester quarts, which should only be filled to within 1 inch of the top (not counting the neck); the oil, being expansive on increase of temperature, would otherwise overflow. The oil as first collected has a very slight empyrenumatic odour; this is prevented as much as possible by the flowers being enclosed in the inner cylinder to avoid contact with the sides of the boiler. There is also a herby odour noticeable in freshly-distilled oil. If the bottles be put in a very cool place, in the dark, and left *uncorked*, but loosely plugged with cotton-wool, these odours will pass off in about two months. Preferably the bottles should be placed in vessels of cold water up to the neck.

The herby odour is probably due to particles of water of vegetation being held in suspension or in solution. It may be remedied by drying the oil with calcium chloride.

Spirits of wine should not be added to *new* oil; it would cause a slight etherification, the odour of which is very unpleasant.

Oil of Lavender.—The newly-distilled oil is almost colourless, or very pale straw-colour, when viewed in bulk. It is mobile, lighter than water, and of a specific gravity of about 0.876 to 0.880, the lightest and most fragrant, having the lowest boiling point, being the first to come over from the still. It appears to be a mixture, in variable proportions, of oxygenated oils and a hydrocarbon, $C_{10}H_{16}$. It contains in solution a stearoptene, or body identical with camphor.

The oil improves or mellows (like brandy or wine) by keeping. This improvement is distinctly noticeable during the first five years, after which, unless kept under exceptional conditions, it deteriorates, oxidises, and resinifies; this can be prevented by admixture of 20 per cent. of grape-spirit.

Re-distillation or rectification is said to improve the quality, but this is very questionable. The author thinks the less it is submitted to the action of heat the better. However, if he wished to rectify it, the first step would be to wash it thoroughly by agitation with an equal volume of cold water in which a little carbonate of magnesia had been mixed, allow it to rest in a cool place to separate, then draw off the supernatant oil, and distil it with an equal bulk of fresh water in a vacuum still at a low temperature, the heat being applied by a steam jacket, and the distillate collected in two portions, the first four-fifths being retained, and the remaining fifth kept apart as inferior.

By reason of its high price, the English oil of lavender is frequently met with in commerce adulterated largely with the French oils of *L. vera* and *L. spica*. This can be detected by comparing a sample of known purity with the suspected sample. Apart from the keen sense of smell possessed by accustomed buyers (and acquired by experience), the boiling points, specific gravities, and optical effects under the polariscope (which are different with all these oils) can be observed.

When the density is below 0.87 there is reason to suspect adulteration.

The pure oil is completely soluble in three volumes of alcohol of a specific gravity of 0.894; a less solubility indicates that it contains oil of turpentine.

The presence of alcohol may be detected by agitating the oil with a few small pieces of dried calcium chloride; these remain unaltered in a pure essential oil, but dissolve in one containing alcohol, and the resulting solution separates, forming a distinct stratum at the bottom of the vessel.

When only a very little alcohol is present the pieces merely change their form, and exhibit the action of the solvent on their angles or edges, which become more or less obtuse or rounded.

Santaline (the yellow colouring matter of santal-wood) is nearly insoluble in pure oil of lavender, and exerts no marked influence on it, but it is freely soluble in oil of lavender adulterated with alcohol or rectified spirit.

By distilling in a water-bath any essential oil which has a higher boiling point than spirit, it is certain that if spirit be mixed with it as an adulterant, the spirit will be the first liquid condensed in the receiver (with only a trace of oil). This spirit may be recognised by the smell and taste; should, however, a doubt exist, add to the distillate a little acetate of potash and strong sulphuric acid, when, on heating, acetic ether is formed if alcohol were present. The presence of fatty oils may be readily detected by placing a drop of the suspected oil on a piece of white paper, and exposing it for a short time to moderate heat; if the oil is pure it will entirely evaporate, but if adulterated with a fixed oil a greasy or translucent stain will be left on the paper. Fixed oils will also remain undissolved when the oil is agitated with three times its volume of rectified spirit.

Lavender Perfumery Formulae.—Oil of lavender enters into the composition of many perfumes, but its principal use is for the manufacture of "lavender water." This consists of a solution of the volatile oil in spirit of wine, generally with the addition of a little essence of musk or ambergris, to "fix" the perfume, and a little rose-water or orange-flower water to soften it. There are various formulae, scarcely any two manufacturers adopting precisely the same—oils of rose, bergamot, neroli, cloves, rosemary, &c. being blended in according to taste. The manufacture of good lavender-water is an art of itself, and one of the main secrets in this art is to employ *pure* materials of the finest quality. The spirit employed should be pure French grape-spirit, unadulterated with the spirit from beetroot, potato, or corn. Most of the lavender-water vended by chemists and druggists is a very inferior compound of French oil, English spirit, and cheap civet, with sometimes the addition of oils of geranium and bergamot.

Synthesis of Citric Acid. A. Haller and A. Held. Monit. Scient. 1890, 1221—1225.

This acid was first made synthetically by Grimaux and Adam (Compt. Rend. 90, 1252), afterwards by Kekulé (Ber. 13, 1686), and again by Dunschmann (Inaug. Dissert. Erlangen, 1886). Grimaux and Adam took symmetric acetone dichloride as their starting point; Kekulé made it from malic acid; and Dunschmann began from acetone dicarbonate. The last method was, strictly speaking, not a perfect synthesis because, up to the present time, acetone dicarbonate has only been made from citric acid itself, by treating the latter with concentrated sulphuric acid.

The authors have made citric acid, starting from the ether of aceto-acetic acid. This ether was first chlorinated, forming γ -chloro-aceto-acetic ether. By the action of potassium cyanide upon this, the chlorine was displaced by CN, forming γ -cyano-aceto-acetic ether. By saponification this body was then converted into the ethyl ether of acetone dicarbonate.

The following equations indicate the above reactions:—

The ethyl acetone dicarbonate thus obtained was then converted into the cyanhydrine by the action of hydrocyanic acid, and this, by hydrochloric acid, into ethyl citrate, which, by treating with KOH, yielded potassium citrate, as shown in the following equations:—

Cyanhydrine of ethyl-acetone-dicarbonate.

Ethyl citrate.

Potassium citrate.

From 50 grms. of ethyl- γ -cyano-aceto-acetate the authors obtained a yield of 6.2 grms. of pure crystallised citric acid, whilst about 4 or 5 grms. would probably remain in the mother-liquors.—H. S. P.

On the Oxidation of Gallic Acid. C. Boettinger. *Annalen*, 260, 337—348.

WHEN gallic acid is oxidised by copper sulphate in alkaline solution, acetic and pyrotartaric acid are produced, but the chief products of the action are bodies which combine with phenylhydrazine, and which are insoluble or very slightly soluble in water.

Gallic acid is boiled for half an hour with an alkaline solution of copper sulphate, the thick dark brown liquid deposits a fine precipitate. The filtered solution is acidified with sulphuric acid, and distilled; a small quantity of volatile acid passes over, which consists chiefly of acetic acid, accompanied by a small quantity of what is probably pyrotartaric acid.

The concentrated residue deposits a large quantity of sodium sulphate. The mother-liquor is shaken with one quart of its volume of acetic ether. A black mass resembling carbon is not taken up by the ether and a further quantity of sodium sulphate is deposited. The ethereal solution is separated and filtered, and the acetic ether distilled off. The residue is boiled repeatedly with water to drive off the volatile acids, although, owing to decomposition, this could not be completely done, and was then neutralised with lime water, whereby soluble and insoluble lime salts are obtained.

The insoluble salts contain, besides calcium carbonate, calcium oxalate and a calcium salt of an acid which the author has named gal acid (gal-säure). This acid is not soluble in dilute hydrochloric acid, and is separated by taking advantage of this. It is hardly soluble in cold water, but easily in hot water, yielding a brown solution, which, however, does not deposit the substance on cooling, but this is brought about by the addition of a mineral acid. Nitric acid oxidises it to oxalic acid. Its elementary composition corresponds with the formula $\text{C}_{14}\text{H}_{13}\text{O}_{11}$ or $\text{C}_{14}\text{H}_{12}\text{O}_{12}$, and its derivatives indicate the formula $\text{C}_{14}\text{H}_{10}\text{O}_{12}$ or $\text{C}_{14}\text{H}_{12}\text{O}_{12}$. A lead salt is obtained by adding lead acetate to a solution of the acid; it forms a powdery precipitate, $\text{C}_{14}\text{H}_9\text{Pb}_2\text{O}_{12} + 3\frac{1}{2}\text{H}_2\text{O}$. A barium salt is prepared by precipitating a solution of the acid neutralised with ammonia with a solution of barium chloride; it forms a voluminous precipitate, which shrinks very much on drying (this is characteristic of the salts of this acid); its formula is

$\text{C}_{14}\text{H}_9\text{Ba}_2\text{O}_{12} \cdot 2 \text{H}_2\text{O}$. By the action of bromine on the acid in a cooled aqueous solution, a bromine derivative, $\text{C}_{14}\text{H}_7\text{Br}_2\text{O}_{12} + 4 \text{H}_2\text{O}$, is obtained. When the action takes place at the ordinary temperature, a tetrabrominated compound is produced. The acid combines with hydroxylamine, and yields a nitrogenous compound, which, however, is not an oxime. With phenylhydrazine acetate it yields a brown substance.

Returning to the solution containing the soluble calcium salts, from which the calcium salt of gal acid had been separated. When this is boiled it throws down a precipitate which redissolves on cooling. This precipitate is a calcium salt; the free acid prepared from it has a formula $\text{C}_{14}\text{H}_9\text{O}_9$. The calcium salt has a composition $(\text{C}_{14}\text{H}_9\text{O}_9)_2\text{Ca}$. The barium salt is also precipitated on boiling its solution and redissolves on cooling. Phenylhydrazine acetate gives with it a yellowish-red compound.—A. L. S.

The Principal Constituent of Oil of Polei. M. Pleissner. *Annalen*, 262, 1—37.

SPANISH oil of polei, from *Mentha Pulegium* (Schimmel and Co.) is a light yellow or greenish, moderately thick liquid, with a small recalling that of oil of peppermint. On distilling the oil (62 grms.) under the ordinary pressure considerable decomposition takes place, and below 212° only a small quantity (3 grms.) of a liquid, consisting principally of water, passes over; the fraction boiling at $212-216$ weighs 50 grms., and consists principally of pulegon (see below); between $216-223^\circ$ a small quantity (4 grms.) of a dark yellow liquid distils over and the brownish residue then left in the retort weighs 5 grms.

Pulegon, $\text{C}_{10}\text{H}_{16}\text{O}$, the principal constituent of Spanish oil of polei, can be obtained in a pure condition by fractionating the liquid, boiling at $212-216$, under a pressure of 60 mm. It is an agreeably-smelling oil with an odour somewhat like that of peppermint, and a specific gravity of 0.9323 at 20° ; it is dextro-rotatory, turns yellow on keeping, even in closed vessels, and does not solidify in a freezing mixture of ice and salt. Pulegon is isomeric with camphor, and, like the latter, it shows the behaviour of a ketone; it combines with hydroxylamine, at the same time taking up the elements of one molecule of water yielding *pulegon-oxime*, $\text{C}_{10}\text{H}_{15}\text{O} \cdot \text{NOH}$, a crystalline compound, melting at 157° , which is levo-rotatory $[\alpha]_D^{20} = -83.44$.

Pulegonoxime combines with benzoic chloride to form a crystalline ethereal salt of the composition—

which melts at $137-138^\circ$ with decomposition, and with acetic chloride, the oxime also gives a crystalline compound which melts at 149° , and has the composition—

When pulegonoxime is heated with concentrated hydriodic acid and a little amorphous phosphorus until a reaction sets in and the mixture then kept for some time, it is converted into *pulegonamine*, $\text{C}_{10}\text{H}_{15}\text{O} \cdot \text{NH}$, a compound which is isomeric with menthoneoxime. Pulegonamine combines readily with benzoic chloride, yielding a crystalline benzoyl derivative, $\text{C}_{10}\text{H}_{15}\text{ON} \cdot \text{CO} \cdot \text{C}_6\text{H}_5$, and when boiled with concentrated potash it is converted into pulegon. When a well-cooled solution of pulegon in light petroleum is saturated with dry hydrogen bromide, and the solvent then evaporated at the ordinary temperature, a compound of the composition $\text{C}_{10}\text{H}_{16}\text{O} \cdot \text{HBr}$ is deposited in small colourless crystals, melting at $10-5^\circ$; this substance is reconverted into pulegon on treatment with silver or lead hydroxide, but when reduced with zinc dust and alcohol it yields an oil which has the same composition and almost all the properties of menthon; the only difference between this oil and levo-menthon which could be detected with certainty is a difference in the melting points of their oximes. When the menthon obtained from pulegon is treated with sodium, it behaves like the menthon prepared from menthol, and is converted into a mixture of isomeric menthols, from which by treating with benzoic anhydride, the benzoyl derivative of natural levo-menthol can be obtained in large quantities.

Samples of pure Spanish polei oil (from *Mentha Pulegium*) can be distinguished from oils of less value by means of the crystalline oxime or hydrobromic acid derivative of pulegon: Algerian and American oils do not yield these compounds in a crystalline condition. The fact that menthol can be prepared from oil of polei, which contains neither menthol nor menthen, is perhaps also of interest from a commercial point of view.—F. S. K.

The Alkaloids of Delphinium Staphisagria. C. Stara-Stojanow. Pharm. Zeits. Russl. 1890, 29, 641, 657, 673, 689; Chem. Zeit. Rep. 15, 6.

To obtain the alkaloid of *Delphinium staphisagria* the seeds are ground to powder and extracted with 80 per cent. alcohol. After distilling off the greater portion of the alcohol the residue is treated with its own volume of water, when a resin separates out and the liquid forms two layers, one oily and the other aqueous. The alkaloids are chiefly contained dissolved in the fatty oils, from which they can be separated by shaking with water acidulated with sulphuric acid. The acid solution thus obtained is made alkaline with sodium bicarbonate and extracted with ether, the above aqueous solution being also worked up with it. The alkaloid *delphinine* separates first in beautiful crystals from the ethereal solution, whilst two other products—*delphisine* and *delphinoidine*—remain in solution.

Delphinine forms rhombic crystals melting at 191.8°. It has the formula $C_{31}H_{49}NO_2$. It gives no colour reactions, those stated by previous investigators being due to impurities in the commercial product. The sulphate and nitrate both form microscopic rhombic crystals.

Delphisine separates from the above ethereal solution before the other alkaloid, *delphinoidine*, and can be purified by washing with alcohol and recrystallisation from ether. It forms fine needles, almost insoluble in water, readily soluble in chloroform, and has the probable composition $C_{30}H_{50}NO_2$.

Delphinoidine is separated from the ethereal residue by concentrating it at 40° C. and then adding petroleum ether, when it is obtained as a white flocculent precipitate. When dry it forms a colourless powder, having a bitter taste, almost insoluble in water, readily so in dilute acids. It has the composition $C_{23}H_{41}NO_2$. Its haloid salts and also the nitrate are amorphous, and readily soluble in water.

—C. A. K.

The Colouring Matter of Red Carbolic Acid. E. Fabini. Pharm. Post, 1891, 24, 2, 25, 41, and 105; Chem. Zeit. Rep. 15, 25 and 45.

See under III., page 453.

A New Alkaloid from the Seeds of Conium maculatum. E. Merck. Chem. Zeit. Rep. 15, 25.

THE highest boiling portions of crude conium contain a new base, which can be separated by repeated fractional distillations in vacuum and subsequent crystallisation. It crystallises in needles melting at 98°, and dissolves readily in alcohol, ether, and chloroform; it boils at 230°–233°, and has the composition $C_{17}H_{17}NO$. It is therefore isomeric with conhydrine, and the name pseudo-conhydrine has been suggested by Ladenburg, who has examined the alkaloid.

—C. A. K.

Muawinum, a New Alkaloid. E. Merck. Chem. Zeit. Rep. 15, 25.

MUAWINUM is the name given to an alkaloid contained in the muawi tree, which is found in Mozambique. The rind of the tree is supposed to possess similar tonic properties to the sassy bark (*Erythrophloeum guineense*), but is quicker and more powerful in its action. The free alkaloid is amorphous and syrup-like, readily soluble in alcohol, ether, and chloroform, and closely resembling erythrophleine.

None of the salts have been obtained in a crystalline condition. The hydrobromide is a white powder, soluble in water, alcohol and chloroform. The physiological action of muawinum is similar to, but not identical with, that of erythrophleine.—C. A. K.

A New Codeine Derivative. E. Merck. Chem. Zeit. Rep. 15, 25.

IN the preparation of apocodeine a second crystalline base is formed which closely resembles codeine. It is a strong base, and differs from apocodeine in its power of crystallisation. It is distinguished from codeine by its high melting point (182°), by being less soluble than codeine in the ordinary reagents, in the crystalline form both of the free base and of its hydrochloride, and by its being precipitated by ammonia both from the hot and cold aqueous solutions of its salts in the form of small needles. Its physiological action is similar to, but less powerful than, that of codeine, so that it does not appear likely to be of any therapeutical value.—C. A. K.

New Alkaloids from Sabadilla Seeds. E. Merck. Chem. Zeit. Rep. 15, 48.

THE author has isolated two new alkaloids, *Sabadine* and *Sabadinine*, from sabadilla seeds.

Sabadine is obtained pure by decomposing its nitrate with a solution of sodium carbonate and then extracting the separated base with ether. The freshly precipitated alkaloid dissolves readily in ether and crystallises from this solvent in short needles. In the crystalline condition the base is difficultly soluble both in water and in ether. The crystals melt with decomposition at 238°–240° C., whilst the portion of the same that dissolves in ether possesses no definite melting point and is left behind after evaporating off the ether in the form of a gum, which becomes crystalline. The base crystallises best from alcohol, as a porcelain-like mass, melting at 238°–240°; a gum-like modification was observed in this case.

When the alcoholic solution is allowed to evaporate slowly, well-defined crystals are deposited. Sulphuric acid (conc.) first gives a yellow colouration with a greenish fluorescence, which latter gradually disappears, whilst the colouration changes to blood-red and then to violet. Concentrated nitric acid does not appear to effect any change. The base produces sneezing, but to a less marked degree than veratrine; its composition corresponds to the formula $C_{29}H_{51}NO_3$. The hydrochloride crystallises from water in white needles, containing two molecules of water of crystallisation which they lose at 101° C.

Sabadinine is got from the sulphate by decomposing it with sodium carbonate and extracting the base with either ether or chloroform. It separates from the former solvent, in which it is difficultly soluble, in the form of hair-like needles, which begin to melt at 160° and decompose gradually on further heating. The alkaloid is fairly soluble in water, readily so in alcohol. Concentrated sulphuric acid produces a stable blood-red colouration, whilst concentrated nitric acid is without effect. The base does not give rise to sneezing. Analysis points to one of the two formulæ $C_{27}H_{43}NO_3$ or $C_{27}H_{45}NO_3$. The hydrochloride forms well-defined crystals, which contain water of crystallisation and are readily soluble in cold water.

Both *sabadine* and *sabadinine* are characterised by remaining dissolved when separated from their salts by the addition of alkalis, alkaline carbonates, or ammonia, and only being precipitated, in a flocculent form, on warming the solution.—C. A. K.

Preparation of Bromoform. M. Denigés. Répért. de Pharm. 1891, 47, 12.

ONE hundred cc. of soap-lye and 100 cc. of water are mixed together and 20 cc. of bromine added. When the reaction has ended the mixture is treated with a sufficient quantity of acetone (10 cc.) to remove the yellow colour of the

hypobromite. A liquid, almost colourless layer of bromoform separates, which is separated, washed, and rectified. The portion of boiling point 118—150 is pure bromoform. The yield is only 60—70 per cent. of theory, owing to some of the bromine being lost as bromide and bromate of sodium. The process is analogous to that of Suilliot and Raynaud for the preparation of iodoform (this Journal, 1889, 210 and 177).—C. A. K.

Californian Soap Plant. H. Trimble. Amer. Journ. Pharm. 1890, 62, 600.

THE Californian soap plant (*Chlorogalum pomeridianum*) belongs to the natural order *Liliacea*, and is found on the Pacific coast between Oregon and Central America. The tubers of the plant produce a lather when placed in water and are greatly valued by the Indians and Mexicans as a substitute for soap. This property is due to the presence of saponin in the tubers, which in the dried state contain up to 6.25 per cent.; they also contain a red-brown crystalline glucoside which is soluble in water and may be extracted with ether.—C. A. K.

The Preparation of Aurous Chloride. J. Löwe. Dingl. Polyt. J. 279, 167.

THE author finds that a solution of auric chloride when evaporated to dryness on the water-bath always gives a small quantity of metallic gold, the amount depending upon the time the operation lasts. He ascribes this to the formation of aurous chloride, which decomposes in contact with water into auric chloride and metallic gold. If a solution of pure auric chloride be heated uninterruptedly on the water-bath in a porcelain basin, a brown deposit will separate. This increases according to the length of time the heating is continued. Whilst the solution darkens from the formation of this deposit, dull dark brown crystals, probably of auro-auric chloride, appear, and after some time the whole contents solidify and form a dark half-amorphous, half-crystalline mass. On further heating light yellow points appear on the dark residue and these gradually pass into a light yellow powder of aurous chloride. The conversion of auric into aurous chloride takes place only slowly at the temperature of boiling water; a gold chloride solution prepared by dissolving 4 grms. of pure metallic gold in aqua regia required several days' heating to completely convert it into aurous chloride.—J. B. C.

PATENTS.

Improvements in the Manufacture and Production of Hydroxyl or Peroxide of Hydrogen, and in the Apparatus Employed thereon. F. Bale, Droitwich, and T. C. Sims, Cheltenham. Eng. Pat. 3628, March 7, 1890. 8d.

BARIUM carbonate, alone or mixed with charcoal, coke, or small coal, is heated in a retort or other suitable vessel to a white heat, whereby "carbonic acid and oxide of barium" are formed. A stream of air, steam or other gas may be passed over it to aid its decomposition. The resulting barium oxide is either allowed to cool somewhat in the same vessel or reheated to a lower temperature in another vessel, and air, preferably purified, or oxygen, is passed in, barium peroxide being formed. The product is suspended in ice-cold water and decomposed by a stream of carbon dioxide, which may be derived from the decomposition of another portion of barium carbonate in a second retort, or may be of extraneous origin. The precipitated barium carbonate is collected and used over again, starting, as before, with the preparation of barium oxide. The operation may thus be made continuous, and the barium carbonate used repeatedly.—B. B.

Improved Process and Apparatus for the Production of Oxygen Gas. R. D. Bowman, East Dulwich. Eng. Pat. 7851, May 20, 1890. 11d.

POWDERED manganese peroxide is added to molten caustic soda with constant stirring until a granular plastic mass is obtained. This is then dusted over with black oxide of copper and heated to full redness in a current of air. The granulated fragments are placed in retorts arranged to work in two sets alternately, and air and steam alternately passed in. As the steam enters the first retort the oxygen which is first evolved and which is diluted with air passes through pipes to an automatic cock. This has only one delivery port whilst the shell has two, opening respectively to the by-passes connected to the two series of retorts. The impure mixture thus passes to the other series of retorts in which the oxygen is absorbed. The pure oxygen which is now coming off from the first series passes, owing to the continued automatic rotation of the cock, to the cooler and thence to the gas reservoir. As soon as all the oxygen has come off steam is cut off from the first series and air passed in, communication with the nitrogen exhaust being opened. Meantime steam is travelling through the second series and so the cycle of operations begin "de novo." It is claimed also that, by the partial oxidation and reduction thus employed, the form of the granules are much more permanent than if a complete conversion took place in each series of operations. The patentee makes no general claim to the production of free oxygen by the action of alternate currents of steam and air upon manganate of soda. For details of the apparatus the specification and drawings must be consulted.—S. G. R.

ERRATUM.

In April number of this Journal, page 382, bottom of second column; for the formula there given for Geranial substitute—

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

Photography in the Colours of Nature. F. E. Ives. J. Franklin Inst. 131, 1—21.

HELIOCHROMIC processes (processes of photography in natural colours) are of two kinds. In one the light itself produces the colours upon the sensitive plate. In the other, light does not produce colours, but regulates their distribution and combination.

The author refers to the results obtained by Seebeck in 1810, by Niepce de St. Victor, Becquerel and Zenker, and thinks that the older productions were better in colour. He comes to the conclusion that there is no scientific basis for a belief that any material improvement can ever be made in processes depending upon the production of colours by the light upon the sensitive plate.

The author then reviews the other kind of heliochromic processes and mentions a paper of H. Collen (British Journal of Photography, October 27, 1865), which he considers to

be a first step towards a solution of the problem of heliochromy, and amounting to a suggestion to make three photographic negatives, one by the action of red, one by yellow, and one by blue light. He then describes the process patented in 1868 by Ducos du Hauron, of Paris, very similar to Collen's, but no more practicable. The suggestions of C. Cros and Poirée, of Paris, of a similar nature could not be carried out, because no photographic plates were sufficiently sensitive to yellow, orange and red rays.

It was only the discovery of colour sensitisers by Vogel which supplied the means for carrying out either Collen's or Poirée's idea. Passing on to the progress made by Duhaumont and Albert, the author mentions the attempt of F. Stolze to solve the problem by the use of three suitable selective colour screens in connexion with colour sensitive plates and of a fourth ordinary negative. The plan of Vogel to sensitise plates specially for each region of the spectrum is too complicated, and could not be carried out for want of the necessary dyes.

In February 1888 the author demonstrated a procedure based upon the observation that all the colours of nature can be counterfeited to the eye by three tints, and mixtures thereof. The process was proved by photographing the spectrum. Promising results were obtained, but the solution of the problem was incomplete until a new principle was discovered which permitted to reproduce not only the spectrum, but also all the hues of nature. This new principle, first announced in November 1888, is that of making sets of negatives by the action of light rays in proportion as they excite primary colour sensations, and images or prints from such negatives with colours that represent primary colour sensations. The principle involves, according to Maxwell's measurements, the production of one negative by the joint action of the red, orange, yellow, and yellow-green rays in definite proportions to represent the red sensation, one by the joint action of the orange, yellow, green, and green-blue rays, in definite proportions to represent the green sensation and one by the joint action of the blue-green, blue, and violet rays, in definite proportions to represent the blue sensation.

Negatives of the required character can be made by exposing a Cyanine-stained gelatin-bromide plate through a double screen of Chrysoidine orange and Aniline yellow of suitable intensity for the red sensation, a Cyanine-erythrosin gelatin-bromide plate through a screen of Aniline yellow of suitable intensity for the green sensation, and an ordinary gelatin-bromide plate through a double screen of Crystalline yellow and Methyl violet R R for the blue sensation.

The plates and screens are correct when they will secure negatives of the spectrum showing intensity curves substantially like the curves in Maxwell's diagram.

There are two ways of making the heliochromic pictures from these negatives. The first method does not produce a permanent picture, but a screen projection.

Lantern slides made from the heliochromic negatives and exactly reversing their light and shade must also represent the effect of the object upon the respective colour sensations. One lantern positive, when seen by transparency in red light, reproduces the effect of the object upon the primary red sensation. Another, viewed in the same manner by green light, reproduces the effect of the object upon the green sensation. The third, viewed by blue-violet light, reproduces the effect upon the blue sensation. Evidently, the combination of these three images into one must form a reproduction of the object as seen by the eye, correct in form, colour, and light and shade. Such a combination is effected by projecting the three pictures with a triple optical lantern so that they exactly coincide upon the screen.

The process is capable of giving results which are above criticism. The most serious objection to this method of solving the problem is that its only commercial value would lie in its application to the illustration of popular lectures.

In the projecting method, the luminous image is built by adding light to light. White light is produced by the mixture of the three coloured lights used for projection, and

black by their suppression. But when by the process it is intended to produce permanent pictures, the paper which may form the basis of the picture is itself white, and it is the shadows that are built up by the superposition of colour prints.

Nevertheless, the colour print has exactly the same function to perform as the lantern positive, *i.e.*, to absorb and suppress, by its shading, light affecting one primary colour sensation. If three positives be removed from the lantern, the screen is evenly illuminated with white light. If the one representing the green sensation be replaced, its shadows will absorb the green light, with the result that the screen bears a picture in the complementary colour, pink, on a white ground. In the colour print method, the first step, a white surface, which corresponds to the fully illuminated screen, and the shadows of the colour print representing the green sensation, when laid upon this surface, absorb the same kind of rays as the shadows of the positive in the lantern, and with the same result, a pink monochrome picture on a white ground. Superposing the other two colour prints upon the first one on paper is like inserting the other two positives in the lantern. This explains why the primary sensations are represented by prints having shades of the complementary (absorbing) colour. It is the lights and not the shades of the colour prints that represent the effect upon the respective primary colour sensation. It is only necessary to use dyes that completely absorb red light, but neither green nor blue-violet for the print representing the red sensation, green but neither red nor blue-violet for the green sensation, blue-violet but neither red nor green for the blue sensation, in order to obtain from the author's negatives a colour print heliochrome that exactly fulfils all theoretical requirements, provided that it be examined in the same kind of white light that is obtained in the screen projections, by mixing red, green, and blue-violet rays. The dyes mentioned by the author in his paper of November 21st, 1888 (Prussian-blue, Magenta, and Aniline yellow), fulfil this requirement, and colour print heliochromes made therewith according to his instructions must, therefore, reproduce all the colours of nature under the conditions of illumination just stated.

This is, then, a theoretically perfect and, at the same time, practicable process of reproducing all the colours of nature in permanent prints from three negatives. Composite heliochromy must always remain a comparatively costly process when carried out in a manner calculated to yield the finest results, and can most profitably be brought before the public in the form of optical lantern lecture illustrations, not with the triple lantern, but with transparent colour print heliochromes mounted as lantern slides. If the colour prints are made by the Woodbury-type process, such heliochromic lantern slides, infinitely superior to hand-painted ones, can be made in quantity at a cost not exceeding one dollar each.—D. H.

Photography in Colours. G. Lippmann. *Compt. Rend.* 112, 274—276.

THE author has succeeded in photographing the image of the spectrum in its true colours, using only the sensitive substances, developers, and fixing agents hitherto employed for photographic purposes.

The sensitive film employed must be transparent and free from grain visible under the microscope, or if the film is granular to any extent, the size of the grains must be negligible in comparison with the length of a wave of light. For this reason ordinary photographic plates cannot be used, but the author has prepared plates employing albumen, gelatin, or collodion as the substratum and iodide or bromide of silver as the sensitive medium, which are almost transparent, possessing only a faint blue opalescence. The plate thus prepared is placed in contact with a reflecting surface of mercury in a suitably arranged cell, in which the film side of the plate is in contact with the mercury. The exposure, development, and fixing of the plate is conducted as usual, and the result, in the case of the spectral colours, is a coloured image which is permanent to the most intense lights. This image is a positive by reflected and a negative

by transmitted light. In the former case the original spectral colours are seen in their due order, in the latter each is represented by its complementary colour.

This result is due to the interference of the incident ray of light, and that reflected from the surface of the mercury, whereby a series of luminous maxima and dark minima are formed within the film. The maxima alone affect the plate so as to render the sensitive medium amenable to development, and at these points a deposit of metallic silver is formed after development. The film is thus divided up by a number of thin deposits of silver, separated from one another by the distance of the points of maximum action, that is, by the distance of half a wave length of the incident light. These deposits are therefore situated at exactly the distances required to produce the originally incident light when looked at by reflexion.

The colours are of the same nature as those of soap-bubbles, but they are purer and more brilliant when a good reflecting surface of silver has been got; this is essentially the case when the number of reflecting surfaces is large. A sensitive film $\frac{1}{100}$ mm. thick will contain about 200 thin deposits of metallic silver.—C. A. K.

XXII.—EXPLOSIVES, MATCHES, Etc.

PATENTS.

Improvements in Explosives. H. H. Lake, London. From S. H. Emmens, Emmens, Penn., U.S.A. Eng. Pat. 3852, March 11, 1890. 4d.

The inventor steepens unsized paper or paper pulp for two minutes in the mixture of nitric and sulphuric acids used in the manufacture of gun-cotton, then washes it with cold water and places it in a solution of ammonium carbonate until effervescence ceases. The paper is then removed to another bath containing a strong solution of picric acid heated to 100° C., in which it is left for ten minutes. After removal from the picric acid solution it is exposed to the action of gaseous ammonia, when the adhering picric acid is converted into ammonium picrate. After drying the material is ready for use as an explosive.—W. M.

Improvements relating to the Manufacture of Explosives, and to Apparatus therefor. H. H. Lake, London. From H. S. Maxim, Vienna, Austria. Eng. Pat. 5209, April 3, 1890. 1s. 3d.

This is a long and complex specification copiously illustrated by drawings. In the manufacture of nitroglycerin according to this invention the acids and glycerin are mixed by injectors operated by cold compressed air, both liquids coming into contact when in the form of fine spray, and in the presence of air which is rapidly expanding, and being blown into and conveyed through a mixing pipe from 100 to 200 ft. in length and $1\frac{1}{2}$ in. in diameter at the part surrounding the injector, increasing, about 20 in. from the injector to 3 in. in diameter. This part of the pipe is surrounded by a water jacket, and finally delivers into a tank containing a large quantity of water. The chemical reaction is completed during the passage of the liquids through the pipe, which has a fall of 1 in 15, and a jet of water is injected into the pipe just before the contents discharge into the tank containing the water.

When the space available is not sufficient for this long mixing pipe, the injectors are arranged over a tank containing the acid mixture which is drawn out of the tank and re-discharged into it, having in its course met with the glycerin in the form of fine spray. When cotton is being nitrated the material is fed in the form of long rolls to a carding wheel which revolves in the mouth of a tube communicating with an injector worked by cold compressed air. The suction draws the cotton in the form of single fibres into the acid.

Smokeless powder is produced by moistening the gun-cotton with ether, acetone or other suitable solvent and then mixing it with nitroglycerin previously mixed with castor oil. The mixture is then treated with acetone vapour in a chamber from which the air is exhausted. The material is then thoroughly kneaded in a special machine and afterwards pressed through suitable dies to form rods or strips of the desired shape.

The inventor states that explosive material composed of 75 parts of gun cotton, 21 parts of nitroglycerin, and 1 part of oil cannot be efficiently worked with rolls, when produced by the processes hitherto adopted, a much larger proportion of nitroglycerin being required to make the material soft enough to be worked; but according to this invention any desired composition can be made in such a manner that it can be easily worked between rolls.—W. M.

Improvements in Percussion Fuses. R. Low, London. Eng. Pat. 5535, April 11, 1890. 8d.

This invention "relates to percussion fuses wherein an annular or tubular piece or guard is so fitted upon the needle, striker, or pellet that it will keep the needle and the cap or detonator out of contact with each other until the projectile or shell is discharged from a gun, when the said guard will be forced backward upon the needle or pellet by the shock of the discharge, so that both the said needle or pellet and the guard are free to move forward upon impact of the shell." The specification is illustrated by drawings.—W. M.

Improvements in the Manufacture of Explosives. C. O. Lundholm, Stevenson, Ayr, N.B., and G. H. Hosie, Saltcoats, Ayr, N.B. Eng. Pat. 7301, May 10, 1890. 4d.

NITRO-CELLULOSE, nitro-oxy-cellulose, or nitro-hydrocellulose is mixed with aniline, toluidine or other suitable amine, and after subjecting the mixture to heat and pressure it forms a clear celluloid mass which may be worked in various shapes. The amine may afterwards be dissolved out either wholly or in part, or other bodies may be incorporated with the explosive, such as potassium nitrate, hydrocarbons, and their nitro-derivatives, nitro glycerol and carbon.—T. A. L.

XXIII.—ANALYTICAL CHEMISTRY.

INORGANIC CHEMISTRY.—QUALITATIVE.

Boiler Feed-Water containing Magnesium Chloride.
A. Goldberg. Chem. Zeit. 15, 31.

See under I., page 118.

Action of Hydrofluoric Acid on Gutta-Percha. W. Hampe. Chem. Zeit. 14, 1777.

HYDROFLUORIC acid gradually attacks gutta-percha, taking up organic matter and sometimes alkalis. Where the acid is used in the determination of ferrous salts in silicates, the results on titrating with permanganate will evidently be too high, after mixing the hydrofluoric acid and sulphuric acid in the process. Therefore, the author adds just sufficient potassium permanganate to colour, and then proceeds as usual. All error is best avoided by keeping the acid in platinum bottles.—T. L. B.

Sulphuretted Hydrogen Free from Arsenic. W. Hampe. Chem. Zeit. 14, 1777.

For ordinary analytical purposes sulphuretted hydrogen may be freed from arsenic by passing through two or three wash-bottles containing a solution of caustic soda or sodium

sulphide. For special purposes the gas is best generated by the action of dilute sulphuric acid (1 to 10) on crystallised sodium sulphide free from arsenic.—T. L. B.

Freeing of Chlorine from Admixed Hydrochloric Acid.
W. Hampe. Chem. Zeit. **14**, 1777.

This is sometimes done by passing the gas over heated manganese dioxide, but the author prefers to use a strong solution of potassium permanganate. The removal is declared to be complete.—T. L. B.

An Oxide of Gold. W. Hampe. Chem. Zeit. **14**, 1778.

Using a fine sheet of gold as positive electrode in a sulphuric acid or nitric acid solution, the author found that the same became coloured brown, and finally a reddish-brown powder fell to the bottom of the electrolysing dish. This was proved qualitatively to be a hydrate of gold formed by the oxidising action of the electrolytically-evolved oxygen. On drying over sulphuric acid, and then heating, it exploded violently.—T. L. B.

Silver Peroxide. W. Hampe. Chem. Zeit. **14**, 1779—1780.

By electrolysing a concentrated solution of silver nitrate the author obtained, as long ago as 1873, a crystalline deposit at the positive pole. A quantity of this crystalline body, which evolves a quantity of oxygen under water, was kept in a sealed tube. After some years the tube exploded, evolution of oxygen being doubtless the cause. The substance contains silver nitrate, which persistently remains in combination. The formula $\text{AgNO}_3 \cdot 4\text{AgO} \cdot \text{aq.}$ has been proposed, but this the author cannot accept as correct; he considers that a mixture of various bodies is present.

—T. L. B.

INORGANIC CHEMISTRY.—
QUANTITATIVE.

A Study in Thermo-Chemistry: the Reduction of Metals from their Ores. W. N. Hartley. Scient. Proc. Roy. Dublin Soc. 1891, **7**, 35—42.

See under X., pages 467—468.

The Carbon of Spiegel Iron. B. Rathke. Ann. **260**, 333—337.

BERZELIUS has observed that when spiegel iron is dissolved by oxidising agents, there remains a residue closely resembling humic substance, inasmuch as it is acid and dissolves partly by alkalis to a brown solution. It appeared to the author that a further investigation of this residue would throw some light on the mode in which the carbon was combined with the metal. A ferro-manganese was employed containing 66 per cent. of manganese. The metal was finely powdered and oxidised with bromine in a flask with a condenser attached; the distillate contained, besides bromine, some carbon tetrabromide together with a little tetrachloride produced from chlorine present as an impurity in the bromine. The chief proportion of the carbon remained in the residue as a black powder, and was purified by treatment with hydrochloric acid. It was then carefully washed and dried; 30 grms. of ferro-manganese yielded 3.7 grms. of this residue. In appearance it resembled gunpowder, and coloured soda solution but slightly. It was digested with hydrofluoric acid, and washed until the wash-water gave no acid reaction, although the powder itself still continued to reddens litmus paper. An analysis of the dried powder gave the following:—Carbon, 49.97 per cent.; hydrogen, 2.12 per cent.; bromine, 21.25 per cent.; chlorine, 1.47 per cent.; oxygen, 25.19 per cent. A weighed quantity of the purified powder was boiled with sodium carbonate and filtered. The filtrate was evaporated to dryness and ignited,

and the bromine and chlorine in the residue determined; 13.94 per cent. of bromine and 1.58 per cent. of chlorine had been removed from the original substance.

The residue weighed 92.19 per cent. of the original substance, and contained: Carbon, 50.71 per cent.; hydrogen, 2.13 per cent.; bromine, 7.41 per cent.; sodium, 7.39 per cent.; oxygen, 32.36 per cent.

As it was possible that the sodium might be present as sodium bromide absorbed by the carbon, some of the original carbon was digested with a concentrated solution of sodium chloride, when it was found that practically none was absorbed by the carbon.—A. L. S.

Determination of Titanium in Ores. W. A. Noyes. J. Anal. and Appl. Chem. January 1891; Eng. and Mining J. 1891, 474.

For a quantitative determination by Weller's method (Ber. **15**, 2592), 0.1 grm. of the finely powdered mineral is mixed in a platinum crucible with 0.2 grm. of sodium fluoride, also finely powdered. 3 grms. of sodium pyrosulphate are then added without mixing. The mass is carefully fused and heated gently till effervescence ceases and copious fumes of sulphuric acid are evolved. This takes only two or three minutes. When cold the mass in the crucible is dissolved in 15 to 20 cc. of cold water and the solution filtered. The filtrate and washings need not exceed 30 cc. If a residue remains it can be treated again by the same method after burning the filter, but the amount of titanium found by a second fusion is usually very small.

To the solution 1 cc. of hydrogen peroxide and a few cc. of dilute sulphuric acid are added, and the colour obtained is compared with that of solutions containing known amounts of titanium. For a standard solution, titanous oxide is dissolved in hot concentrated sulphuric acid and the solution diluted till 1 cc. contains 1 mgrm. of TiO_2 . In diluting it is best to use dilute sulphuric acid at first, to prevent the precipitation of titanous oxide.

The author cannot entirely confirm Weller's statement that the colours produced are not affected by small amounts of iron. He finds that even 2 mgrms. of ferric oxide in the form of sulphate have a very decided effect on the tints produced, especially when the amount of titanium is small. It is advisable, therefore, to add to the comparison tubes an amount of ferric sulphate corresponding approximately to that in the solution which is tested. A solution of iron ammonium alum answers well for this purpose, and all that is necessary is to match the colour of the solution of the mineral before adding hydrogen peroxide to it. If this be done, titanium can be readily determined in the presence of very considerable amounts of iron. Thus, 0.02 mgrm. of titanous oxide can be detected in 30 cc. of water in the presence of 0.1 grm. of ferric oxide in the form of sulphate. This would correspond to 0.02 per cent. for 0.1 grm. of a mineral.

A qualitative test for titanium can be made in five minutes as follows: Mix a little of the powdered ore with sodium fluoride, add sodium pyrosulphate and fuse as above. Cool by dipping the crucible in cold water. Add two or three cc. of dilute sulphuric acid and 10 cc. of water. Dissolve by boiling. Divide the solution into two portions, and to one add a few drops of hydrogen peroxide. A comparison with the solution to which no hydrogen peroxide has been added will show at once whether titanium is present or not.

This method works very well with magnetite and other iron ores.

Volumetric Determination of Oxygen by means of Nitrogen Oxide. L. de Koninck. Zeits. f. angew. Chem. 1891, **78**—80.

This paper deals with Wanklyn and Cooper's (see also this Journal, 1890, 980) application of Priestley and Cavendish's method for estimating oxygen by means of nitric oxide. The author's investigations on this method lead him to the conclusion that it is inapplicable for analytical purposes,

the results varying between 77 and 122 per cent. of the theoretical quantity, and depending to a great extent on the quantity of the reagents employed.

A priori, a mixture of air and nitric oxide, in presence of water, should react according to the equation—

And therefore the contraction following the mixing of the two gases will be the measure of the oxygen originally present, the disappearance of three volumes being equivalent to one volume of oxygen. However, the author's figures for contraction vary between 2.32—3.17 volumes when using air, 2.86—3.76 volumes when using oxygen containing 17.6 per cent. of nitrogen, and 2.93 volumes for pure oxygen. From these considerations, the reactions represented by the following equations become probable:—

In fact the presence of nitric oxide in the gas mixture is accompanied by an increase in the quantity of nitrous acid formed. In absence of nitric oxide, nitric acid alone is formed. Dilution with indifferent gases also favours the formation of nitrous acid.

The nitric oxide required is obtained from dilute nitric acid (sp. gr. 1.11) and copper foil, and the precaution is adopted of shaking the gas with water in the burette to absorb any nitrogen peroxide formed. Two Winkler-Hempel burettes, containing measured volumes of the gases, are then connected by means of a capillary tube filled with water, and the oxygen is thus introduced in the nitric oxide burette.—H. A.

A New Method for the Analysis of Silicates. P. Jannasch. Meeting of the Chemical Society, Heidelberg, January 23, 1891. *Chem. Zeit.* **15**, 150.

THE powdered silicate is placed in a platinum vessel of special construction, moderately concentrated hydrochloric acid added, and the whole enclosed in a hard glass tube and heated at 190—200° for 10—15 hours. The details of the method will be given in a special communication. The advantages claimed for the method are a saving of time and also of substance, since the alkalis and other constituents can be determined in one and the same quantity of the substance.—A. K. M.

The Analysis of Chrome Iron Ore. R. Namias. *Stahl u. Eisen*, 1890, **10**, 977.

ONE gram of chrome iron ore is mixed with 8—10 grms. of acid sodium or potassium sulphate in a platinum crucible, and the whole kept in a state of fusion for one hour. 2—3 grms. more of acid sulphate are then added, after allowing to cool, and the heating continued for a few minutes. This second fusion suffices to convert any basic sulphates that may have been formed during the prolonged heating, into neutral sulphates. The melt is extracted with water and hydrochloric acid, and the silica separated as usual; if it contains any chromium, the fusion must be repeated. One-third of the filtrate from the silica is taken for the determination of the chromium. It is first neutralised with caustic alkali, and then treated with 0.5 gm. of magnesia, suspended in water and warmed. The precipitate, after being filtered, washed, and ignited, is fused in a platinum crucible with potassium chlorate and fusion mixture (potassium sodium carbonate), the melt extracted with water, and the solution of chromate thus obtained reduced and precipitated with ammonia.

To determine the manganese, one-tenth of the filtrate from the silica is tested colorimetrically, after removing the chromium by means of barium carbonate, the sulphuric acid present being first precipitated with barium chloride.

The iron is determined volumetrically by potassium permanganate. The colour due to the chromium salts does not interfere as long as the solution is sufficiently dilute.

—C. A. K.

Arsenic in Phosphorus. W. Hampe. *Chem. Zeit.* **14**, 1777.

THE author has found as much as 0.53 per cent. of arsenic in sticks of phosphorus.—T. L. B.

Estimation of Sulphur in Lead. W. Hampe. *Chem. Zeit.* **14**, 1778.

ABOUT 50 grms. of lead, in the condition of filings, are gradually added to 100 grms. of nitric acid, kept molten in a porcelain crucible. Oxidation is complete in about an hour, the mass being stirred from time to time. The melt is poured out, a current of carbon dioxide is then passed into hot water containing it, after which the whole is boiled up and filtered. The solution again has carbon dioxide passed into it to remove the lead completely, and the filtrate is then evaporated down on the water-bath. The nitrate is got rid of by hydrochloric acid in the usual way, and the sulphur determined as barium sulphate. Results obtained are reliable.—T. L. B.

The Employment of Bromic Acid in Quantitative Analysis. W. Feit and K. Kubierschky. *Chem. Zeit.* **15**, 351—352.

THE use of bromic acid, more particularly, in volumetric analysis, is based on its great oxidising power; and on the fact that it liberates from potassium iodide an equivalent amount of iodine which may be accurately titrated with a standard solution of sodium thiosulphate. In effecting an oxidation bromic acid is reduced to bromine thus:—

In practice a solution of potassium bromate is employed, 30 grms. of the salt are dissolved in about 300 cc. of water, and the solution is boiled with sufficient sulphuric acid to decompose any potassium bromide that may be present, in accordance with the equation—

The solution is cooled and diluted to 1,000 cc. Two cc. of the solution are mixed with potassium iodide and sulphuric acid in excess, and the liberated iodine is titrated with sodium thiosulphate. The bromate is then further diluted so that 1 cc. of it equals 10 cc. of decinormal thiosulphate. In carrying out an analysis, an excess of bromate solution, acidified with sulphuric acid, is placed in a graduated flask, the solution of the body to be analysed is added, and the whole is boiled for five minutes to expel the liberated bromine. The liquid is cooled, diluted to the mark, and the residual potassium bromate is determined in an aliquot part of the solution in the manner indicated above.

The method is applicable to the estimation of sulphur in mono- and poly-sulphides, sulphurous, and thiosulphuric acids (all of which are completely oxidised to sulphuric acid), nitrous and oxalic acids, iron in ferrous salts, &c. It is hardly necessary to point out that the solution to be analysed must contain no chlorine, bromine, or iodine compounds. The test analyses given are quite satisfactory.

—H. T. P.

The Estimation of Dissolved Oxygen in Water. W. Kisch. *Zeits. f. angew. Chem.* 1891, 105—108.

L. W. WINKLER (this Journal, 1889, 727) gives a method of estimating dissolved oxygen in water. This has led the author to make a critical examination of the existing methods, viz., (a) the Bunsen-Tiemann, (b) Mohr's, and (c) the Schützenberger-Risher.

Three sets of experiments were made with each method on (1) water direct from the main; (2) the same water after agitation with air; and (3) distilled water after agitation with air; the result being that the author

considers Winkler's method to give good and accurate results, and in addition, to be the easiest and most reliable method. Methods (b) and (c) gave very similar results, while (a), the Bunsen-Tiemann, gave undoubtedly too low results, for which the author was unable to account.

He recommends Winkler's method as the most practical and simple for the estimation of dissolved oxygen in water.

—D. A. S.

Determination of Albuminoid Nitrogen in Water.

E. Wagner. *Jour. Pharm. Chim.* 1891, **23**, 5.

KJELDHAL'S method is well adapted for determining nitrogen in water, contaminated with animal refuse. To prevent loss of nitrogen through the action of free nitric acid on the organic substances, the water must first be deprived of this acid. This is effected by using Gladstone and Tribe's zinc-copper element, which reduces nitric acid to nitrous acid and finally to ammonia. Strips of zinc are dipped into a 3 per cent. copper sulphate solution washed with distilled water and dried as soon as there is a sufficient deposit of copper formed. Before use these strips are moistened with distilled water. About 500 cc. of the water to be analysed is filled into a glass-stoppered bottle, acidified with sulphuric acid, and about 25 sq. cm. of the element left in the water until metaphenylenediamine is no longer coloured yellow. After removing the strips, the water is evaporated to a small volume, filled into a 100 cc. flask with a long neck, and still further evaporated, until about 5 cc. are left.

On cooling .05 grm. of cupric oxide and 10 cc. of a mixture of 6 parts of ordinary with 4 parts of fuming sulphuric acid are added and the mixture heated gently at first and finally boiled. The reaction is complete as soon as the liquid is coloured a clear green. Water is now added and a slight excess of a solution which contains 300 grms. of caustic soda and 350 grms. of seignette-salt in one litre; generally 60 cc. are sufficient to produce an alkaline reaction. The ammonia is then distilled off and titrated.—A. R.

ORGANIC CHEMISTRY.—QUALITATIVE.

Testing Ferrum Citricum Oxidatum. H. Warnecke.

Pharm. Zeit. **35**, 784.

ACCORDING to the Ph. Germ. III, ferric citrate only gives a deep blue colouration and not a precipitate of Prussian blue on addition of potassium ferrocyanide to its aqueous solution; the precipitate only forms on the addition of hydrochloric acid. The addition of hydrochloric acid is also advisable in testing ferric citrate for ferrous citrate by means of potassium ferriocyanide.—C. A. K.

Glycerinum. Ph. Germ. III. E. Ritsert. *Pharm. Zeit.* 1890, **35**, 802.

THE silver nitrate test for the purity of glycerol is conducted as follows:—A mixture of equal parts of the sample and of ammonia are heated to boiling, with constant stirring. The flame is then removed and the silver solution added, when there should be no deposition of metallic silver and no yellow colouration after standing for five minutes.—C. A. K.

Santonin. T. Salzer. *Pharm. Zeit.* **35**, 808.

SANTONIN (0.01 grm.) when shaken with 1 cc. of sulphuric acid and 1 cc. of water is said to give no colouration, but on addition of one drop of ferric chloride solution a violet colouration results. The author states that the addition of the acid always gives a yellow colour to the solution, and that the violet colouration only forms after boiling, this being probably due to the fact that the santonin must first be converted into iso-santonin before the reaction can take place.—C. A. K.

New Test for Sesamè Oil in Olive Oil. Lalande and Tambon. *J. Pharm. Chim.* [5], **23**, 231.

THE reaction with hydrochloric acid containing sugar being unreliable, the following is proposed:—15 cc. of oil are shaken up in a test tube for a couple of minutes with 5 cc. of colourless nitric acid of sp. gr. 1.4; a yellow colouration of the acid on settling indicates presence of sesamè oil. Olive oil, earth-nut oil, and cotton-seed oil leave the acid colourless. In some cases, as, for instance, with old olive oil used for machinery, a yellowish colouration may be obtained without sesamè oil being present. But if the nitric acid be carefully decanted and cleared, the presence of sesamè oil is confirmed by the formation of a turbidity on addition of water.—T. L. B.

Guaiacol. Pio Marfori. *Gass. Chim.* 1890, **20**, 537.

ONE part of guaiacol dissolves in 60 cc. of water, the solubility being decreased by any impurities present and by an increase in the boiling point of the substance. Heated with chloroform and solid caustic potash pure guaiacol gives a purple-red colouration, whilst the impure product gives a less marked reaction. With sulphuric acid (conc.) the pure product gives a stable purple-red colouration, but the least impurity detracts from the purity of the colour formed. 3—4 cc. of guaiacol given to a dog, appeared in the urine in the form of guaiacol-sulphuric ester.—C. A. K.

Testing Oil of Bitter Almonds. E. Merck. *Chem. Zeit.* **Rep.** **15**, 26.

THE author points out that the presence of chlorine in artificial benzaldehyde in the form of chlorinated products does not serve to distinguish it from the natural oil of bitter almonds, because the latter does at times contain chlorine compounds, whilst, further, the artificially prepared product is obtained to-day practically free therefrom.—C. A. K.

The Value of Furfuraldehyde (Furfural) Reactions for the Detection of Fusel Oil in Spirits. Neumann-Wender. *Zeit. f. Nahrungs-mittel-Untersuch. u. Hygiene*, **5**, 1.

THE author's experiments on the subject point to the following conclusions:—

1. Jorissen's test is not sufficiently delicate, because it only indicates the small quantity of furfuraldehyde contained in the fusel oil. Also it is not reliable, because furfuraldehyde is formed in all fermentative processes, and passes over with the products of distillation. In cases of sweetened or coloured brandy, or when essences have been added, the product must be first distilled, and this renders the test useless.

2. The diamidobenzene reaction of Uffelmann is open to the same objections as the above, because it also is really only a test for the furfuraldehyde.

3. Muller's and also Ekmann's test for fusel oil is unreliable because ethereal oils and other admixtures also colour concentrated sulphuric acid, and therefore the comparison with the colouration produced with pure amyl alcohol is inaccurate.

4. Uffelmann's test by means of the spectroscope is not reliable in presence of ethereal oils.

5. Udransky's furfuraldehyde reaction (this *Journal*, 1889, 309) is only of value when the sample contains no products, beyond amyl alcohol, which give any colouration either with sulphuric acid alone or with sulphuric acid and furfuraldehyde.—C. A. K.

ORGANIC CHEMISTRY.—QUANTITATIVE.

The Examination of Commercial Toluidine. F. F. Raabe. Chem. Zeit. **15**, 116 and 179—80.

With the view of introducing a uniform method for the commercial examination of toluidine, the author gives a detailed account of the method proposed by himself.

The toluidine is first examined with regard to its colour and cleanness, and also to that of a solution of 10 cc. of the toluidine in 10 cc. of hydrochloric acid and 80 cc. of water. 100 cc. of toluidine are then distilled from a flask of 180—200 cc. capacity, to which is fitted a two-bulb tube holding the thermometer, the position of the latter being so adjusted that the upper end of the bulb is 0.5 cm. below the lower edge of the side tube: the rate of distillation recommended is two drops a second. The specific gravity is determined either by weighing or by means of a hydrometer (Lunge, this Journal, 1885, 339). Of the various methods employed for determining the amount of paratoluidine present, the author states that, with certain precautions, Schoop's acetyl method can be employed with samples containing 30 per cent. or more paratoluidine. The oxalic acid method as modified by Lorenz (Annalen, **172**, 190) also gives very good results. A simple method, devised by the author, consists in adding known quantities of paratoluidine to the sample under examination, and then determining the temperature at which the mixture solidifies. For this purpose a thermometer with a range from 30 to 50 and divided into $\frac{1}{2}^\circ$, is employed. With this method it is possible to detect differences of 0.2 per cent. paratoluidine. As in the other methods, it is necessary that the toluidine be free from water.—A. K. M.

On the Oxidation of Tanning Materials. R. Jahoda. Zeits. f. angew. Chem. 1891, 104—105.

See under XIV., page 472.

On the Estimation of Indigo. F. Voeller. Zeits. f. angew. Chem. 1891, 110—111.

F. Mohr's method for the estimation of indigo by means of potassium permanganate often leads to incorrect results on account of organic impurities present in indigo, which by reduction of permanganate show too high a percentage of indigo. Indigo is on this account frequently adulterated with reducing agents such as oxalic acid. The same fault applies to all the other oxidation methods. The reduction methods of Pugh and Frische, in which indigo is converted into Indigo-white and back to indigo, gives too high results, on account of other bodies usually present in commercial indigo, which are similarly affected.

Berzelius found that unadulterated indigo contained, in addition to indigo and ash, three other bodies which he named Indigo-gluten, Indigo brown, and Indigo-red. He extracts the above-mentioned bodies by treatment with hydrochloric acid or acetic acid, then with alkali, and finally with alcohol and hot water, after which the purified indigo is weighed. It is a rule, however, still contains silica and other mineral matters giving too high a result. The author modifies Berzelius' method. He extracts the pure indigo in the above way and estimates the nitrogen in it by Kjeldahl's method, and calculates the true percentage of indigo therefrom, the factor being 9.36. He found a difference of 0.175 per cent. nitrogen between commercial indigo and that purified by Berzelius' method, which he assumes to belong to the three above-mentioned constituents. Calculating all the nitrogen to Indigo-gluten by multiplying by the factor 6.25, it corresponds to 1.09 per cent. The complete analysis of a sample of commercial indigo gave—

	Per Cent.
Indigo	75.76
Mineral matter	16.35
Moisture	6.48
Indigo-gluten, &c. containing nitrogen	1.41

The author found 99.85 per cent. of indigo in purified and sublimed indigo by this method.—D. A. S.

Ipecacuanha and Emetin. E. M. Arndt. Apoth. Zeit. **5**, 780. IPECACUANHA contains, together with emetin, a volatile base, which on examination proved to be cholin. The quantity of emetin does not exceed 1 per cent., and may be determined in the following way:—10 grms. of the powdered root are ground up together with 5 grms. of sodium carbonate and 1 gm. of dry ferric chloride, and the whole extracted on the water-bath with 100 grms. of 60 per cent. methyl alcohol for one hour. The alcohol is distilled off after filtering the solution, and the residue taken up with 50 cc. of dilute ammonia water. This alkaline solution is extracted with chloroform, and the chloroform solution treated with acidulated water, which takes up the emetin. The solution thus obtained is then titrated with a potassium mercuric iodide solution, 1 cc. of which corresponds to 0.0189 gm. of emetin.—C. A. K.

On Italian Wines. C. Niederhäuser. Pharm. C. H. N. F. 1891, **12**, 15.

See under XVII., page 475.

ANALYTICAL AND SCIENTIFIC NOTES.

Heat Conductivity of Solutions. G. Jaeger. Rep. d. Phys. 1891, **27**, 42.

THE results show that all solutions of salts are worse conductors of heat than water is, the diminution in conductivity being proportional to the quantity of salt. A mixture of salts dissolved in water brings about a diminution equal to the sum of the diminutions due to the constituents separately.—T. L. B.

The Solubility of Potassium Bitartrate. C. Blarez. Compt. Rend. **112**, 334—335.

THE solubility of potassium bitartrate in water is a function of the temperature, and may be calculated by the following formula, in which Q represents the percentage of salt dissolved at any temperature $t^\circ \text{C}$.—

$$Q t = 0.351 + 0.00151 t + 0.00055 t^2$$

For practical purposes the following simpler equation will be sufficiently accurate—

$$Q t = 0.369 + 0.000569 t^2$$

Small amounts of potassium chloride added to a solution of tartar cause the precipitation of precisely equal weights of the latter. This fact is embodied in the formula—

$$Q t = (0.369 + 0.000569 t^2) - \text{KCl}$$

This equation only holds good so long as the potassium chloride added does not exceed the tartar originally present. In presence of larger amounts of potassium chloride the quantity of tartar dissolved depends on the temperature and is inversely proportional to the square root of the potassium existing in the potassium chloride added—

$$Q t = 0.0189 + 0.000005216 t^3$$

$\sqrt{\text{K}}$

Potassium bitartrate is completely insoluble at ordinary temperatures in the following mixture:—

	Parts
Alcohol at 90°	100
Water	1000
Potassium sulphate	4
Tartaric acid	2

If the potassium sulphate in the above solution be completely or partly replaced by potassium bisulphate, the liquid will dissolve tartar.—H. T. P.

APPARATUS.—PATENTS.

An Improved Pinch-Cock for Regulating the Flow of Liquids and Gases in Elastic Tubes. P. Braham, Bath. Eng. Pat. 2658, February 19, 1890. 6d.

THE pinch-cock consists of two plates of any suitable material with V-shaped slots in them, and enclosing an elastic tube. By turning the plates one upon the other the elastic tube is compressed, and can thus be made to regulate the flow of the liquid. The invention is capable of application to feeding bottles, burettes, gas and water pipes, &c. (See this Journal, 1890, 255.)—E. S.

Improvements in Instruments for Estimating, Measuring, or Comparing Colour, Texture, and Appearance of Transparent or Opaque Bodies, and for Testing Colour Vision and Light Perceptive Power. J. W. Lovibond, Salisbury. Eng. Pat. 6221, April 23, 1890. 8d.

THIS instrument, called by its inventor "the tintometer," has been previously described in Eng. Pats. 12,867 of 1886 and 3859 of 1887 (this Journal, 1887, 522; and 1888, 234 and 424). The improvements consist in making the instrument *binocular*, thus giving a better view of the objects under examination, and also of the standard with which it is compared; and, secondly, in rendering the instrument available for testing the colour-vision and light perceptive power of the eye. This is effected by the insertion in the tube of a central removable diaphragm, by which the two eye-pieces are made to command separate fields of view, which may be wholly or partly distinct, and partly common to both eye-pieces, as may be required.—E. S.

New Books.

A DICTIONARY OF APPLIED CHEMISTRY. By T. E. THORPE, B.Sc., Ph.D., F.R.S., Treas. C.S., Professor of Chemistry in the Normal School of Science and Royal School of Mines, South Kensington. Assisted by eminent contributors. In three Volumes. Vol. II. 1891. London: Longmans, Green & Co.; and New York: 15, East 16th Street.

THE notice of the issue of the second volume of this work appeared in this Journal, 1890, 219—220. Volume II. is like Vol. I., a handsomely bound book, 8vo. size, containing list of Abbreviations and of Contributors, followed by subject-matter covering 714 pages. With the text, as in the case of Vol. I., are interspersed numerous exceedingly well-executed wood engravings illustrative of plant, apparatus, &c. The article with which Vol. II. closes is *Nux Vomica*. As examples of specially interesting subjects treated of in this volume may be instanced the following:—EXPLOSIVES, covering 34½ pages and illustrated by wood engravings. The subject embraces the following divisions: *Gunpowder*; its ingredients, Pebble and Prismatic powder, Mining powder, Brown or Cocoa powder. *Gunpowder* containing other nitrates than potassium nitrate, *e.g.*, barium nitrate, sodium nitrate and ammonium nitrate (*Amide powder*). *Gun-cotton*, *Nitrated gun-cotton*, *Tonite*, *E.C. powder*, *Johnson's powder*, *Nitroliquin*, *Nitroglycerin*, *Nitroglycerin preparations*, *Kieselguhr dynamite*, *Mica powder*, *Carbo dynamite*, *Blasting gelatin*, *Gelatin dynamite*, *Gelignite*, *Forcite*, *Judson powder*, &c., &c., *Fulminate of mercury*, *Sprengel's explosives*, *Picric acid and picrates*. *Measurement of the Intensity of Action of Explosives*.

FERMENTATION is the subject of another valuable monograph, covering 31 pages. COAL GAS is the subject of an article occupying 35 or 36 pages, and along with those

following, on OIL GAS and WATER GAS, gives a very complete account of the industry as a whole. The essay on GLYCERIN, by the late Mr. W. Lant Carpenter, is both a striking and a well-illustrated article. The Class of Colouring Matters known as the *Indamines and Indophenols* is treated at considerable length. Other ably treated and interesting articles are those on IODINE, LAKES, LEAD, LEATHER, ARTIFICIAL MANURES, MATCHES, MILK, and NAPHTHALENE.

DIE SYNTHETISCHEN DARSTELLUNGSMETHODEN DER KOHLENSTOFF-VERBINDUNGEN. VON DR. KARL ELBS. A.O. Professor an der Universität Freiburg, i. B. Zweiter Band, Leipzig: Johann Ambrosius Barth, 1891. London: H. Grevel & Co., 33, King Street, Covent Garden.

OCTAVO volume, in paper cover, price 9s. 6d., forming the second volume of the work, the first volume having appeared in 1889 (see this Journal, 1889, 1015). This second volume in fact completes the work. Price for the two vols. is 17s. The text covers 452 pages, and the concluding 19½ pages are devoted to a copious alphabetical index. The second volume is devoted to the treatment of two branches of the subject, *viz.*, *Syntheses by decomposition (Abspaltung)*, and *Syntheses by Electrolysis*.

The *Syntheses by decomposition* are subdivided as follows:—I. *Syntheses by separation of hydrogen*. II. *By separation of oxygen*. III. *By separation of sulphur*. IV. *By separation of nitrogen*. V. *By separation of halogen*. VI. *By separation of halogen-hydrogen*. VII. *Syntheses through separation of water*. VIII. *By separation of hydrogen and water*. IX. *By loss of water and halogen-hydrogen*. X. *By loss of sulphuretted hydrogen*. XI. *By loss of ammonia, or amines, &c.* XII. *Simultaneous separation of several elements in the form of their hydrogen compounds*. XIII. *Syntheses by separation of inorganic acids, with or without simultaneous separation of water or halogen-hydrogen, &c.* XIV. *Syntheses by separation of organic acids, with or without simultaneous separation of water or halogen-hydrogen, &c.* The latter part of the work is devoted to the subject of *Syntheses by Electrolysis*.

COAL, AND WHAT WE GET FROM IT. A ROMANCE OF APPLIED SCIENCE. Expanded from the Notes of a Lecture delivered in the Theatre of the London Institution, January 20th, 1890. By RAPHAEL MELDOLA, F.R.S., F.I.C., &c., Professor of Chemistry in the Finsbury Technical College, City and Guilds of London Institute. London: Society for Promoting Christian Knowledge, Northumberland Avenue, Charing Cross, W.C.: 43, Queen Victoria Street, E.C. Brighton: 135, North Street. New York: Ed. J. B. Young & Co. 1891.

SMALL 8vo. volume, price 2s. 6d., part of a series known as the "Romance of Science Series." This particular book is dedicated to Dr. W. H. Perkin, F.R.S., "The founder of the Coal Tar Colour Industry." The author taking his work to be a presentation in popular form of an account of the industry which has arisen out of the great waste from gasworks, says of it, "In the strictest sense it is a romance of dirt." Yet dissatisfied with the superficial way in which the subject is often treated in lectures to popular audiences, the author has endeavoured to go somewhat beyond this and give some notion of the scientific principles underlying the subject of coal and its products. After the Preface and Table of Contents, follow the subject-matter, covering 204 pages, and Alphabetical Index. The text is illustrated by several well-executed wood engravings, and some interesting diagrams and tabulated matter.

DIE PRÜFUNG DER CHEMISCHEN REAGENTIEN AUF REINHIT.
VON DR. C. KRAUCH. Zweite gänzlich umgearbeitete
und vermehrte Auflage. Berlin: Verlag von Julius
Springer, 1891. London: H. Grevel and Co., 33, King
Street, Covent Garden.

THIS work appears to be one specially designed for
manufacturers of pharmaceutical chemicals, though in some
respects its scope extends beyond that of the branch
referred to. It is an 8vo. volume, bound in cloth, price
6s., and the present issue forms the second and revised
edition. The volume opens with an Introduction followed
by that to the first edition, and then by the one to the
second edition. The text fills 246 pages, and the work
concludes with an alphabetical index of the latinised terms
followed by one of the German names of the reagents and
chemicals treated of in the book. Not only are the quali-
tative methods of examination given, but also the most
practical and useful quantitative methods.

ELEMENTARY LESSONS IN HEAT, LIGHT, AND SOUND. By
D. E. JONES, B.Sc., Professor of Physics in the University
College of Wales, Aberystwith. London and New York:
Macmillan and Co. 1891.

SMALL octavo volume, bound in red cloth, price 2s. 6d. It
contains Preface, Tables of Contents, Note on the Metric
System of Weights and Measures, and 279 pages of subject-
matter. Page 280 is devoted to Answers to Examples, and
the work concludes with an Alphabetical Index. The book
is well illustrated with some 24 or 25 well-executed wood
engravings. The range of the book is well shown in the sub-
division following:—HEAT.—Temperature, Thermometers,
Expansion of Heat, Specific Heat and Calorimetry, Hygro-
metry, Transmission of Heat, Conduction, Convection, and
Radiation. LIGHT.—Photometry, Velocity of Light, Reflec-
tion of Light, Spherical Mirrors, Refraction of Light,
Lenses, Optical Instruments, Dispersion and Colour.
SOUND.—Vibratory Motion, Wave Motion, Velocity of
Sound, Reflection, Pitch and Musical Intervals, Transverse
Vibration of Strings, Resonance, Vibration of Air Columns,
Organ Pipes.

COLOUR MEASUREMENT AND MIXTURE. By Captain W.
DE W. ARNFA, C.B., R.E., D.C.L., F.R.S. Society for
Promoting Christian Knowledge. London: Northum-
berland Avenue, W.C., and 13, Queen Victoria Street,
E.C. Brighton: 135, North Street. New York: E. and
J. B. Young & Co. 1891.

SMALL 8vo. volume, like the little work on Coal, by
Professor Meldola, belonging to the *Romance of Science*
Series. Price 2s. 6d. It commences with a frontispiece
representing the Colour-patch Apparatus. This is followed
by the title page and preface. In the latter the author
points out that he had some years ago set himself to carry
out three measurements of the spectrum, viz., 1st, the
heating effect; 2nd, the luminosity; and 3rd, the chemical
effect on various salts of the different rays of the spectrum.
He, along with General Festing, was led in the second part
of it, into a wider study of colour than was first intended.
On the invitation of the Society of Arts, Captain Arnfa
delivered a short course of lectures on the subject of Colour,
and in this course the subject was treated from the point of
view of his and General Festing's own methods of experi-
menting, and the lectures expanded and modified now form
the basis of this little volume. The text covers 203 pages,
and the work concludes with an alphabetical index. The
text is illustrated by 14 woodcuts and diagrams.

Trade Report.

(From Board of Trade and other Journals.)

TARIFF CHANGES AND CUSTOMS REGULATIONS.

RECOVERED SULPHUR IN THE UNITED STATES.

The classification of recovered sulphur as refined brim-
stone, subject to duty at the rate of 8 dols. per ton, has
been overruled by the Board of Appraisers, which decides
that the article is entitled to free entry as recovered sulphur.
—*Industries.*

THE NEW RUSSIAN TARIFF.

It is stated upon good authority that the following figures
represent the principal alterations in the pharmaceutical
section of the new Russian tariff, which will come into
force within a few weeks:—

	Roubles per Pound.	
	Present Tariff.	New Tariff.
Carboic acid	0'06	0'20
Benzol.....	0'06	0'20
Tar	0'06	0'10
Tar derivatives	0'06	0'10
Animal fats.....	0'36	0'60
Fish oils (including cod-liver oil) un- purified.	Free	0'75
Spermaceti (crude)	Free	0'75
Spermaceti (refined).....	Free	2'00
Fats (purified), oleum, &c.	Free	1'20
Stearin	Free	2'00
Paraffin.....	Free	2'00
Vaseline (crude)	Free	2'00
Borax (refined)	Free	1'20
Argols (crude).....	Free	0'75
Antimony.....	Free	1'00
Nitrate of soda.....	Free	0'65
Silicate of soda.....	Free	0'50
Caustic soda	Free	0'80
Caustic potash.....	Free	0'80
Caustic potash (refined)	Free	4'00
Quinine and its salts.....	Free	6'00
Castor oil	Free	2'10
Cocoonut oil	Free	1'00
Palm oil	Free	1'00
Crude glycerin.....	Free	1'00
Essential oils (non-alcoholic)	Free	6'00
Collodion	Free	15'00
Fruit essences	Free	15'00
Iodoform	6'00	10'00
Chloral hydrate.....	6'00	10'00
Chloroform	6'00	10'00
Opium.....	13'20	15'00

NEW RUSSIAN TARIFF—continued.

	Roubles per Poud.	
	Present Tariff.	New Tariff.
Lactucarium.....	13'20	15'00
Sulphur (raw)	Free	0'04
Sulphur (refined).....	0'12	0'20
Liquorice juice.....	..	2'50
Soda bicarbonate	0'80
Magnesite (in lump).....	..	0'04
Magnesite (ground).....	..	0'10
Magnesium chloride	0'15
Magnesium sulphate (raw)	0'15
Ether (gross weight).....	..	1'00
Copper sulphate	1'00
Zinc sulphate	1'00
Zinc chloride	1'00
Iron sulphate.....	..	0'50
Silver nitrate	10'00
Phosphoric acid.....	..	6'00
Benzoic acid	6'00
Bromine salts.....	..	6'00
Mercurial salts.....	..	6'00
Bromine.....	..	2'65
Iodine (crude).....	..	2'65
Chlorate of potash	2'40
Potassium permanganate	2'40
Antifebrin.....	..	10'00
Phenacetin	10'00
Gallie and Pyrogallie acids.....	..	6'00
Salicylic acid and Salicylates	6'00
Bismuth salts	6'00
Sugar of milk	5'00
Iodoform	10'00
Iodine salts.....	..	6'00
Antimony sulphide (golden)	3'00
All chemical and pharmaceutical preparations unenumerated.	2'40	2'65

—Chemist and Druggist.

EXTRACTS FROM DIPLOMATIC AND
CONSULAR REPORTS.

NEW GERMAN PATENT LAW.

Sir E. B. Malet, Her Majesty's Ambassador at Berlin, in a despatch to the Foreign Office, dated the 18th April, forwards translation by Mr. Trench of the new German patent law, which is to come into force on the 1st October next. The following is a full copy of this translation:—

First Part.—Patent Right.—Sect. 1. Patents are granted for new inventions which may be turned to account in trade.

No patent can be granted—

1. To such inventions as run counter to the laws of the land or to the laws of morality.
2. To newly invented articles of food, delicacies, or medicines, or substances produced by chemical agency, unless the invention consists in some definite procedure for the fabrication of such substances.

Sect. 2. An invention for which a patent is demanded pursuant to this law is not to be regarded as new if at the time of such demand it is already so described in (German) public prints issued within the last hundred years, or if it has been already so openly employed in Germany ("in *Inlande*") that its employment by other experts would thereby seem to be rendered possible.

The specifications of patents officially published in foreign States are placed on the same footing as the (German) public prints after the lapse of three months from the day of publication in cases where the patent is applied for by the same person who has applied for it in the foreign State, or by his legal representative. This favour, however, extends only to official specifications of inventions in those States whose reciprocity is guaranteed by a notice in the *Reichs-Gesetzblatt*.

Sect. 3. The right to a patent for a new invention rests with the first person who makes application for it pursuant to this law. No later application can establish a right to a patent where the invention is the subject of the patent demanded by the prior applicant. If this is the case in part only the latter applicant has only a claim to receive a patent with such restrictions as may be required in justice to prior applicant.

No claim to a patent is established by an application, the essential part of which is taken without permission from descriptions, drawings, models, implements or machines proceeding from some other person than the applicant, or from some process employed by such other person, and when the latter puts in a protest against the granting of the patent demanded. If such protest leads to the withdrawal or rejection of the application the protestor in case of his demanding a patent for his invention within one month from the receipt of advice from the Patent Office informing him of such withdrawal or rejection, can claim that his application be regarded as dating from the day before the publication of the previous application.

Sect. 4. The patent grants to its possessor the exclusive right in the way of business to manufacture, deal in, sell, or use the thing patented. When a patent is granted for a process its effects extend also to the immediate products of that process.

Sect. 5. The effect of a patent does not extend to a person who at the time of application was already employing the invention in Germany, or had already made the necessary arrangements for employing it. Such person has the right to employ the invention for the use of his own business on his own premises or elsewhere. This right can only be inherited or purchased along with the business itself.

The effect of a patent also ceases with regard to such use of it as is made by order of the Imperial Chancellor in the army or navy, or in any other manner for the benefit of the nation at large. Yet in this case the patentee has a claim to a suitable indemnity from the Empire or from the State for whose special benefit the patent has been restricted.

Such indemnity to be fixed by a court of law if private arrangement should prove unable to determine it.

The effect of a patent does not extend to contrivances in use on vessels which only come to Germany ("in *das Inlande*") at intervals.

Sect. 6. Claims for the granting of a patent and the rights proceeding from a granted patent are inheritable. Both claims and rights can be transferred to other persons *in toto* or in part by contract or by testamentary dispositions.

Sect. 7. The duration of a patent is 15 years, reckoned from the day after that on which it is applied for. If a new invention is made as an improvement on, or a supplement to, a previous invention already patented in favour of the applicant, the latter can demand a supplementary patent to expire at the same time as the patent for the prior invention.

If by the nullification of the original patent a supplementary patent becomes an independent one, its duration and the day on which its fees fall due are determined by the commencement day of the original patent.

The amount of the fees is reckoned from the commencement day of the supplementary patent.

The time which elapses between the day of application for the supplementary patent and the next following anniversary of the commencement of the original patent is reckoned as the first year of the new patent.

Sect. 8. For every patent a fee of 30 marks (about 30s.) must be paid in previous to its being granted (sect. 24, paragraph 1).

Except in the case of supplementary patents (sect. 7), a fee is to be paid on every patent at the beginning of the second and every following year of its duration amounting to 50 marks (2*l.* 10s.) the first time and increasing by 50 marks (2*l.* 10s.) every succeeding year.

This fee (paragraph 2) is to be paid within six weeks of the day on which it falls due. After the expiration of this term payment can be made during a second term of six weeks, but with the addition of 10 marks (10s.) by way of a fine.

To a patentee whose indigence is satisfactorily proved, a respite may be granted by allowing the payment of his fees for the first and second year of the duration of his patent to stand over till the third year, and remitting such payment if the patent lapses in the third year.

The payment of fees before they fall due is allowable. If the patent is withdrawn, declared null, or retracted, the fees paid in advance are returned.

A reduction of the fees may be made by a decree of the Federal Council.

Sect. 9. The patent becomes null and void if the patentee renounces it or if the fees are not paid in due time either to the Treasury of the Patent Office direct or to some post office within the German Empire for transmission to the said treasury.

Sect. 10. The patent is annulled when it is found—

1. That the thing patented is according to sections 1 and 2 not patentable.
2. That the invention is already patented to a previous applicant.
3. That the main contents of the application have been taken from the descriptions, drawings, models, machines, or appliances of another person, or from a process employed by him and without his permission.

Should one of these objections (1, 2, or 3) be found to exist in part only, a corresponding restriction of the patent is to be made.

Sect. 11. The patent can be revoked after the lapse of three years, reckoned from the day on which the grant was published (sect. 27, paragraph 1):—

1. When the patentee has failed to carry out his invention to a satisfactory extent within Germany ("im Inlande") or when he has neglected to take the necessary steps to secure its practical carrying out.
2. When it appears desirable for the public welfare that permission should be given to others to use the invention, and the patentee refuses to grant such permission for a suitable indemnity and under sufficient securities.

Sect. 12. Persons not residing in Germany ("im Inlande") have no claim to the granting of letters patent, nor can they exercise the rights granted to patentees otherwise than by a duly appointed representative in Germany ("im Inlande"). The latter is entitled to act as their attorney, both in proceedings under this law and also in civil suits regarding the patent, as well as to demand fines and punishments.

The place where the representative resides, or, failing this, the place in which the Patent Office has its seat, is to be regarded (in accordance with sect. 24 of the civil "*prozessordnung*") as the place where the property ("*vermögensgegenstand*") exists.

With the consent of the Federal Council, the Imperial Chancellor is entitled to order the exercise of the right of retaliation against the subjects of a foreign State.

Second Part.—Patent Office.—Sect. 13. The granting, revoking, and annulling of patents is committed to the Patent Office.

The Patent Office has its seat at Berlin. It has a president, members who have qualified themselves for the office of judge or for the higher administrative service (*jurisprudents*), and members versed in one particular branch (*experts*). The members are appointed by the Emperor, the president by the Emperor on the recommendation of the Federal Council. The appointment of the jurispudent members is, when they hold an office in the Imperial or State service, for the term of such office, in the other case for life. The experts are appointed either for life or for a term of five years. To the latter, the regulations in sect. 16 of the law of the 31st March, 1873, touching the legal relations of the Government officials of the German Empire do not apply.

Sect. 14. In the Patent Office there are:—

1. Departments to consider the applications made for patents.
2. A Department to consider demands for the nullification or revocation of patents; and
3. Departments for complaints and grievances.

In the Applications Departments only such experts may serve as have been appointed for life.

The experts of the Applications Departments may not serve in other Departments, nor the experts of the latter in the Applications Departments.

In the Applications Departments the presence of at least three members, two of whom must be experts, constitutes a quorum.

For the decisions of the Nullification Department and of the Departments for Complaints and Grievances, it requires two jurispudent and three experts to form a quorum.

For other decisions the presence of three members suffices.

The regulations of the civil "*prozessordnung*" with regard to challenging those charged with the conduct of a trial are here also duly observed.

Experts who are not members may be called in to participate in the deliberations, but may not vote.

Sect. 15. The decrees and decisions of the Departments are given in the name of the Patent Office; they must be accompanied by the reasons which have led to them, must be set down in writing, and sent officially to all the parties concerned.

Sect. 16. Against the decisions of the Applications Departments and the Nullification Department complaints may be laid. In the consideration of a complaint, no member may take part who was concerned in the decision complained against.

Sect. 17. The formation of the Departments, the demarcation of their spheres of action, the form of their proceedings, the manner of conveying their decisions, and the business routine of the Patent Office will, whenever this law fails to make due provision, be regulated, with the consent of the Federal Council, by an Imperial decree.

Sect. 18. The Patent Office is bound, at the request of the law courts, to give its opinion on questions concerning patents whenever, in the course of legal proceedings, the opinions of experts differ from each other.

In other cases the Patent Office is not authorised to make decisions or give opinions outside its proper sphere of business without the approval of the Imperial Chancellor.

Sect. 19. At the Patent Office a register is kept, giving the subject and duration of the granted patents, as well as the names and residences of the patentees, and of such representatives as they may have appointed. The commencement, expiration, lapse, nullification, and revocation of patents must be entered in the register, and at the same time published in the *Reichsanzeiger*.

Personal changes of patent holders or their representatives, when announced to the Patent Office in a proper form, will also be registered and published in the *Reichsanzeiger*. Until this has been done, the former patentee or his representative retains his rights and liabilities as established by this law.

The inspection of the specifications, drawings, models, and specimens on the basis of which patents have been

granted, is free to everyone, except where a patent has been taken into use for the army or navy in the name of the Imperial Government.

The Patent Office publishes the essential part of all such specifications and drawings as are permitted to be inspected by everyone, in an official journal. In this journal will also be found the notices which this law requires to be published in the *Reichsanzeiger*.

Third Part.—Proceedings in regard to Patents.—Sect. 20. Applications for the granting of a patent for an invention must be made in writing, and must be addressed to the Patent Office. For each separate invention a separate application is necessary. The application must contain the request for a patent, and must clearly define the thing to be patented. In an annexed specification the invention must be so described as to make its use by other experts appear possible. Accompanying the specification must be a statement of what is claimed as patentable in the invention. The necessary drawings, diagrams, models, and specimens must also be sent in along with the application.

The Patent Office gives directions as to any further requirements regarding applications.

Previous to the decision for publishing the application, alterations in the same are permitted. Along with the application, 20 marks (about 1*l.*) are to be paid for the costs of the proceedings.

Sect. 21. The application is submitted to a preliminary examination by one member of the Applications Department.

Should the preliminary examiner find that the application does not fulfil the prescribed requirements (sect. 20), he advises the applicant of the deficiencies, and requests him to make good the same within a fixed period of time.

Should it appear from the preliminary examination that the invention is not patentable in the sense of sections 1, 2, and 3, paragraph 1, the applicant will be informed of this opinion and the reasons on which it is grounded, and will be requested to reply within a given space of time.

If the applicant fails to apply in due time, the application is regarded as withdrawn; if he replies in time, the Applications Department proceeds to a decision.

Sect. 22. If the prescribed requirements (sect. 20) have not been fulfilled, or if it appears that the invention is not patentable according to sections 1, 2, and 3, paragraph 1, the application is rejected by the Department.

In this decision the preliminary examiner, who has charged the applicant to make good deficiencies in his application, or to defend the patentability of his invention, is not allowed to take part.

If an application is to be rejected on grounds not already communicated to the applicant by the preliminary examiner, opportunity must be granted to him to express himself concerning these grounds within a stated period.

Sect. 23. If the Patent Office finds the application correct and the grant of letters patent not impossible, it decrees that the application shall be published. From the moment of this publication, the legal consequences of the patent (sections 4 and 5) as regards the subject of the application take effect provisionally for the benefit of the applicant.

The publication is made by a single insertion in the *Reichsanzeiger* of the applicant's name and the essential part of the demand contained in his application. Along with this publication notice is given that the subject of the application is temporarily protected against employment by others than the applicant.

At the same time the application, with all its supplements, is exposed for public inspection at the Patent Office. By the authority mentioned in sect. 17 of this law, it may be decreed that the application shall be exposed for public inspection at other places besides Berlin.

On the demand of the applicant the exposure for public inspection may be continued for a period of not more than six months. Exposure for as much as three months may not be refused.

In the case of an application made in the name of the Imperial Government for the protection of an invention to be employed in the army or navy, a patent may on demand be granted without any publication, in which case no entry is made in the Register of Patents.

Sect. 24. The first annual fee (sect. 8, paragraph 1) is to be paid within two months from the date of publication (sect. 23). If payment is not made during this period the application is to be regarded as withdrawn.

Within the same period protest may be raised against the granting of a patent. The protest must be delivered in writing, and must be accompanied with reasons.

It can only be based on the assertion that according to sections 1 and 2 the object is not patentable or that according to sect. 3 the applicant has no claim to receive a patent.

In the case mentioned in sect. 3, paragraph 2, only the injured party is entitled to protest.

After the expiration of the fixed time the Patent Office must decide as to the granting of a patent. In this decision the preliminary examiner who has charged the applicant to make good the deficiencies of his application or to defend the patentability of his invention (sect. 21) may not take part.

Sect. 25. In the preliminary examination and in the proceedings before the Applications Department the summoning and *ex parte* hearing of the parties, the examination of witnesses and experts, as also the taking of such other steps as may seem necessary to elucidate the matter under consideration, may at all times be resorted to.

Sect. 26. Against the decision by which an application is rejected the applicant can put in a protest, and against the decision as to the granting of a patent the applicant or the complainant can put in a protest in either case within one month after being informed by the Patent Office of the decision in question.

Along with the presentation of the protest 20 marks (about 1*l.*) are to be paid in for costs of proceedings; if this payment be not made the protest is regarded as not presented.

If the protest is in itself contrary to regulations, or if it be raised too late, it will be rejected as inadmissible.

If the protest be found admissible the further proceedings are regulated by sect. 25.

The summoning and *ex parte* hearing of the parties must be resorted to if demanded by one of them. This demand can be refused only when the party making it was already summoned to the proceedings before the Applications Department.

If the decision on the protest is to be based on other grounds than those taken into account in the decree complained against, the interested parties must have a previous opportunity granted them for expressing themselves thereupon.

It is left to the free judgment of the Patent Office to decide to what extent the costs of the protest shall be borne by the party whose case is rejected, and also whether the protest fee (paragraph 1) shall be returned to the party whose protest is found justifiable.

Sect. 27. When the granting of a patent is definitely determined on, the Patent Office makes the fact known in the *Reichsanzeiger* and then provides the patentee with letters patent.

If the application is withdrawn after its publication (sect. 23) or if a patent is refused this must also be made known.

In these cases the prepaid annual fee will be returned.

If a patent is refused, the preliminary protection is regarded as not having taken place.

Sect. 28. Proceedings for annulling or retracting a patent are only commenced when a complaint is raised against it.

In the case of sect. 10, No. 3, only the injured party has the right to lay a complaint.

In the case of sect. 10, No. 1, no complaint is allowable after the lapse of five years from the day on which the granting of the patent was published (sect. 27, paragraph 1).

The complaint must be made in writing and addressed to the Patent Office; it must state the facts on which it is based.

Along with the complaint a fee of 50 marks (about 2*l.* 10*s.*) is to be paid in. If this payment is not made no complaint is judged to have been received.

The fee is returned if the proceedings are terminated without summoning the parties.

If the complainant resides in a foreign country he must, on the demand of his opponent, find securities for the costs of the proceedings. The amount of such security is left to the free decision of the Patent Office, which informs the complainant of the sum demanded as security and the time within which it must be paid. If the security demanded is not paid within the time fixed the complaint is regarded as withdrawn.

Sect. 29. When it has been determined to commence proceedings the Patent Office informs the patentee of the complaint, and requests him to answer it within a month.

If the patentee fails to answer within the time fixed a decision may be formed at once without summoning or hearing the parties, and every fact advanced by the complainant may be regarded as proved.

Sect. 30. If the patentee replies in time, or if in the case of sect. 29, paragraph 2, the Patent Office does not at once decide according to the complaint laid, the necessary steps are taken by the Patent Office for elucidating the matter, in the former case the reply of the patentee being communicated to the complainant. The Patent Office may order the hearing of witnesses and experts who are then subject to the same regulations as in proceedings before the courts of civil law. The proceedings must be taken down by a sworn recorder.

The decision is made after the parties interested have been summoned and heard.

If a patent is to be revoked on the basis of sect. 11, paragraph 2, the final decision to do so must be preceded by the threat of revocation accompanied by reasons and fixing suitable term for deliberation.

Sect. 31. In the decision (sections 29 and 30) the Patent Office must determine, according to its free judgment, in what manner the costs of the proceedings are to be borne by the parties.

Sect. 32. The law courts are bound to lend judicial aid to the Patent Office, and on demand to impose fines on witnesses and experts who fail to appear or who refuse to testify or take oath, as well as also to command the appearance of witnesses.

Sect. 33. An appeal is permissible against the decisions of the Patent Office (sections 29 and 30).

Appeals go to the *Reichsgericht*. They must be sent to the Patent Office in writing within six weeks from receipt of decision, and must state the grounds of dissatisfaction.

In its sentence the law court has also to determine the question of costs with the same liberty as is granted to the Patent Office in sect. 31.

For the rest, the proceedings in the law court will be conducted according to regulations to be drawn up by the law court, and approved by Imperial decree, with the consent of the Federal Council.

Sect. 34. With respect to the language to be employed at the Patent Office, the regulations of the *Gerichtsverfassungsgesetz* regarding the language of the law courts apply also here. Written communications not drawn up in the German language will not be taken notice of.

Sect. 35. Any person who knowingly or in culpable ignorance makes use of an invention contrary to sections 4 and 5 is bound to compensate the injured party.

In case of an invention for a process for manufacturing some new substance, every substance of like composition is to be regarded as made by the patented process until the contrary is proved.

Fourth Part.—Penalties and Indemnities.—Sect. 36. Any person who knowingly makes use of an invention contrary to sections 4 and 5 is punishable by a fine not exceeding 5,000 marks (250*l.*), or by imprisonment not exceeding one year.

Prosecution is only resorted to when demanded. The withdrawal of a demand for prosecution is permissible.

If a punishment is decreed, the injured party is at the same time empowered to publish the sentence, at the expense of the condemned. The manner of publication and its limits as to time must be defined in the sentence.

Sect. 37. Instead of any and every indemnity obtainable under this law, an amercement not exceeding 10,000 marks

(500*l.*) may be adjudged to the injured party on his demanding it. Each and all who are jointly condemned to such amercement are answerable for it with all their goods and chattels.

An adjudged amercement excludes the admissibility of all further claims for indemnification.

Sect. 38. In civil suits, where a plaintiff or defendant bases a claim on the provisions of this law, the decision is referred to the *Reichsgericht* as a last court of appeal according to sect. 8 of the introductory statutes of the law for the constitution of courts (*Gerichtsverfassungsgesetz*).

Sect. 39. Complaints of the infringement of patented rights fall under the statute of limitation after three years as regards each separate act on which they are grounded.

Sect. 40. A fine not exceeding 1,000 marks (50*l.*) is incurred by—

1. Whoever places a mark on wares or the packing of wares which is calculated to produce the mistaken belief that such wares are protected by a patent under this law.
2. Whoever in public advertisements, on signboards, on business cards, or by any other means of publicity makes use of a mark calculated to produce the mistaken belief that the wares thereby offered or alluded to are protected by a patent under this law.

Art. 2. The regulation given in sect. 28, paragraph 3, of Article 1 applies also to already existing patents with the restriction that complaints are admissible only within a period of three years from the day on which this law comes into force.

Art. 3. This law comes into force on the 1st October 1891.

THE GERMAN PATENT OFFICE IN 1890.

(*Chem. Zeit.* 15, 180.)

The number of applications for patents during the past year was 11,882, showing an increase of 237 over the previous year. The annual numbers, starting with 1886, are as follows: 9,991, 9,904, 9,869, 11,645, and 11,882, the increase in the last years being possibly due to the greater confidence felt in the present conduct of the Patent Office. The number of patents granted was 4,680, that is, 39.5 per cent. of the applications, those granted during 1889 numbering 3,882.

A table shows the numbers of applications and patents granted in each of the 89 classes, and a good deal of other information of more or less local interest is also given.

The receipts of the Patent Office amounted to 2,080,713 marks, and the expenses 810,038 marks.—A. K. M.

PHOSPHATE MINING IN CAROLINA.

Mr. C. St. John, Her Majesty's Consul at Charleston, South Carolina, in his last report to the Foreign Office, gives the following information respecting phosphate mining, phosphates and fertilisers of Carolina:—

The phosphate mining and fertilising industry, so important a factor in the trade of Charleston and the State of South Carolina, has proved itself more profitable to those engaged in it this year than in any previous one, notwithstanding the discovery and partial development of the Florida rock deposits.

There are good reasons, however, why Carolina rock should maintain its ground. The supply is regular and of uniform quality, it has a high percentage of phosphate of lime, is low in carbonate, iron, and alumina, is of good colour when calcined, becomes crisp and dries well after being treated with acid, without afterwards absorbing moisture and becoming lumpy, and moreover it is easy to grind.

During the year phosphates and fertilisers were produced to the amount of 790,000 tons.

The year has been a very good one for the fertiliser business, the sellers having nearly their own way up to the end of the season. The companies have doubled their capacity during the year, new companies being formed, and the fertiliser interest more thoroughly advertised than ever among dealers and consumers.

Some of the Charleston's leading bankers have shown their confidence in the prospects of the business, and faith in the future of this town, by organising two new companies—the "Chicora" and the "Imperial."

These will add at least 50,000 tons to the supply for sale next year, and would seem to warrant the establishment of two mining companies to furnish the additional crude rock that will be required.

A favourable feature in this industry is the fact that the Western States, the great granary of the country, are beginning to use the Carolina fertilisers for the production of wheat, corn, barley, and oats. And it is believed that Chicago, Cincinnati, Detroit, Kansas City, and Minneapolis will soon become great fertiliser centres.

The total shipment of manufactured fertilisers from Charleston for the year was 261,650 tons.

The demand for commercial manures, constantly increasing in different directions, necessarily requires the importation of considerable quantities of chemicals used in their manufacture.

The imports of these chemicals during the year ended 30th September 1890 amounted to 33,935 tons, valued at 127,634*l.*—(No. 845, *Foreign Office Annual Series.*)

GENERAL TRADE NOTES.

THE NAPHTHA INDUSTRY OF BAKU.

It appears from the *Message Officiel*, which bases its information upon data received from the naphtha producers, that the industry in this product is greatly developing at Baku. In 1890 the quantity of naphtha extracted at the isthmus of Apcheron reached the figure of 239 million pounds (pound = 36 lb. avoirdupois), including waste, and the quantity of mineral oil employed as combustible. In 1889 the product at the same place was only 205,500,000 pounds; in 1888, 192,600,000 pounds; in 1887, 165,000,000 pounds; in 1886, 150,000,000 pounds; and in 1885, 116,000,000 pounds only. In five years the average of the increase in the production of naphtha has therefore been, in this peninsula, 24,600,000 pounds.

In 1890, it may be remarked, the production of naphtha at Apcheron has exceeded for the first time the production of the same mineral oil in Pennsylvania, which was only 230 million pounds. With the exception of 6,348,700 pounds of naphtha exported from Baku by the Caspian Sea or by the Transcaucasian railway, the remainder of this product has been refined on the spot at Baku. In 1890 there were sent from that port 169,551,300 pounds of different naphtha products, including 67,306,500 pounds of lighting oils, 4,600,900 pounds of lubricating oils, 522,200 pounds of benzene, gasoline, tar, &c., and 97,121,700 pounds of naphtha residues.

TIN DISCOVERY IN MEXICO.

The *South American Journal* for March 28th, has the following:—

Additional news is to hand with respect to the discovery of tin in Durango State by Mr. John Pershmaker, who relates that the vein was revealed almost by accident. He had, it seems, gone to what is known as the Diabolo mine, 45 miles south-west of the capital of the State, for the purpose of examining the yield of metal-bearing ores, not knowing that tin had ever been found there. He found a shaft about 300 ft. deep, which had passed through two light veins of gold, iron, and silver-bearing ores. On making a close examination of the sides of the shaft, he noticed that the miners had passed through a large and very rich lead of oxide of tin, evidently without knowing it. After making his calculations as to the probable direction taken by the vein, he ran a horizontal tunnel for a short distance, striking a vein of ore alleged to be truly remarkable. It is stated to be 4 ft. wide, and composed of a solid mass of oxide of tin, assaying from 50 to 60 per cent. of the pure metal. It is quite free from sulphur, so that the work of reducing the ore simply amounts to the work of smelting and casting into ingots.

THE CONDITIONING OF TEXTILE FABRICS IN FRANCE.

The French *Monde Economique* of the 18th April gives the following information respecting the conditioning of textile fabrics in France:—

The operation of conditioning is one by which the proportion of moisture contained in textile fabrics is determined, as all these fabrics contain a certain quantity, or more correctly speaking, a proportion of moisture varying with the processes to which they have already been subjected, and also their temperature.

It will be easily understood that a salesman who buys his fabrics by weight has a decided interest in keeping them as moist as possible when he sells them by weight. Moreover, as is most frequently the case, this seller is only an intermediary, he cannot without considerable pecuniary risk sell his goods in a dryer condition than when he bought them, and in order to determine their actual proportion of moisture he must refer the matter to a third party. It is therefore necessary to have recourse to an arbitrator—an expert, whose impartiality is above suspicion. This arbitrator is the public condition house, which, officially organised, offers on absolute guarantee of secrecy as regards the transactions revealed to it. The following is the system adopted in arriving at the proportion of moisture:—

For some time it had been remarked that the quantity of moisture contained varied very little for the same fabric when it is placed for a sufficiently lengthened period under the average conditions of atmosphere and humidity. This constant figure seems to be established in the proportion of 9.5 per cent. for silk, 14.50 per cent. for combed or spun wool, 7.80 per cent. for cotton yarn, and 10.70 per cent. for linen. The above proportion, as regards silk, served as a basis for the primary processes employed in silk conditioning. The silk was spread out, and left exposed to the air for a long time in a well-ventilated place. The material was then weighed and the weight found was adopted by the seller and the buyer as the basis of the settlement of their account. This method of procedure could only give an approximation frequently varying with the season, and it will be easily understood what advantages would be derived by a person buying in a dry season and selling in a wet one. On the other hand, this method necessitated the establishment of drying places of considerable extent.

The true principle of conditioning was really established by the works of Talabot and D'Arcet upon the condition houses of Lyons. From their numerous experiences it resulted that silk exposed to a temperature above 100° soon threw off its moisture without in any way injuring its textile properties. The weight of the silk after desiccation was called "absolute weight." Later on, it was recognised that the same system might be adopted for other tissues, such as wool, cotton, and linen; but in order to attain absolute desiccation without injuring the fibres, it was found necessary that the temperature to which they were exposed should be lower than 100°, the point required by silk.

To obtain this weight accurately certain methods were invented by Talabot and perfected by Gamot, by which the weight of the tissues could be obtained while undergoing the drying process. It had been remarked that on emerging from the drying apparatus the textile fibre very rapidly absorbed water, and Persoz, in concert with Rogeat, of Lyons, invented the apparatus now in use generally throughout the whole of France, by which the heating is effected by a current of warm air proceeding from a stove.

Conditioning then really means the determining of the absolute weight of the goods presented for that purpose. To this absolute weight is added the amount agreed upon between the seller and the buyer as representing the quantity of moisture that ought legitimately to be contained and which is known as *réprise*. The total weight thus obtained is the "condition weight," serving as a basis for the making out of invoices.

In principle, the process of conditioning comprises two operations. The first consists in determining by the aid of a drying room how much humidity per cent. is contained in various samples. Experience has proved that when a sample does not exhibit further appreciable diminution in weight after exposure for a period of six minutes it may

be considered as absolutely dry. The weight is then taken independently by two employes, and the material is removed from the apparatus. By a very simple calculation a deduction is made from the primary weight and the absolute weight of the proportion of moisture contained in the sample which is known as the "proof."

The second operation is effected in the offices of the condition houses. This consists in applying the results to which attention has been directed above to the calculation of the condition weight, that is to say, to the amount the proof ought to weigh, and consequently the total weight if it only contained the proportion of moisture recognised as legal or legitimate, or *réprise* as it is called. It has been admitted, and the authorities have adopted it as a legal rate, that this *réprise* in the case of wool should be at the rate of 17 per cent. That means that if the net condition weight of a bale of wool is 117 kilos., there will be found 100 kilos. of wool absolutely dry and 17 kilos. of moisture. This wool therefore contains as moisture 17 out of 117, or 14.530 per cent.

At the same time as they determine the degree of moisture the condition houses indicate, when the article is spun, and when required, the numbering or weighing of the skeins. This number serves to distinguish the degree of fineness of the thread under investigation. The basis of this calculation is either the weight of a constant and uniform length of this thread (in the case of silk), or the length corresponding to a fixed and determined weight, which latter system is adopted for tissues other than silk.

The old category of silk threads was formerly estimated according to the number of coins (*deniers*) that would be required to counterbalance the weight of 100 ells of this thread. In metrical measure the *denier* is equivalent to 53.13 mgrms., and 100 ells correspond to very nearly 176 metres. These *deniers* and ells have no longer any legal value, their signification is even generally ignored, but the laws of routine are always sacred in France; the trade still insists upon these out-of-date expressions, and continues to make use of them now that the metrical system is in general use, as if the latter had never existed. The legal standard is determined by the weight in grammes and fractions of grammes of a skein of 500 metres. At various recent international congresses the opinion has been unanimously expressed (an opinion acted upon by some condition houses) that the category of silk should be determined by the number of decigrammes that 1,000 metres of the thread weigh, or which amounts to the same thing, by the number of grammes that a myrimetre will weigh.

As regards other tissues, it will be found that the numbering of the threads varies not only with the country, but even according to the various districts of each country, and yet nothing can be clearer than the terms of the decree of 1810 prescribing the numbering of threads. These are as follows: "All proprietors of spinning mills are to form skeins of the yarns of cotton, linen, hemp, or wool of a thread of 100 metres in length, and to make the hank of 10 of these skeins, so that the total length of the thread forming the hank shall be 1,000 metres; these threads shall be labelled with the number indicative of the skeins necessary to make up the weight per kilogramme." In short, the number of a thread is expressed by the number of thousand metres necessary to make up the weight of a kilogramme. Instead of saying, for example, of a thread that it is No. 35/2, which in Paris signifies that it requires 35 skeins and two-tenths of a skein to make up a half kilogramme, how much simpler it would be to express it as 50,000 metres. It would be at once understood that with a kilogramme of this thread a length could be made of 50,000 metres. Moreover, this thread, which in Paris is numbered 35/2, is known at Roubaix as No. 35, at Rheims it becomes No. 35/70, at Lyons No. 34/70, and elsewhere No. 17/50.

In all conditioning operations the apparatus used to determine the number of the threads is specially manufactured in Paris or Lyons, and is so constructed as to allow of either 20 or 24 skeins of 250 or 500 metres in length being made. In addition to the actual numbering, the condition houses have also to deal with another operation.

The commercial value of textile fabrics is only really ascertained and determined when the threads have been assayed or conditioned—that is to say, only after the operations of weighing and *décreusage*, or boiling, which determine mathematically the thickness and the regularity of the thread. Moisture is not the only heterogeneous substance which increases the weight of textile fabrics; other substances are also mixed more or less with wool, cotton, and silk, which disappear after washing or scouring of the threads. These foreign substances are sometimes natural and sometimes the result of fraudulent practices. Silk, for instance, while still enclosed in the worm is a compound substance, a fibre wrapped up in an impervious envelope, the chemical composition of which, as is shown by analysis, is analogous to that of *ossein*. This envelope is technically called *grès de la soie*. By the process of boiling, the silk is divested of the *grès* which it contains. Raw wool is also heavily loaded with grease, dust, and other refuse. When worked up, other substances also, which have escaped the washing, are frequently discovered.

The *décreusage* of the silk is effected in the condition houses by two successive boilings in water in which soap of the purest kind is added. The comparison of the actual weight before and after the operation gives the percentage of foreign matter.

Wool is treated in a totally different way to silk. Samples of the raw wool are subjected to a scouring process, with a view to determine the actual condition of the mass. Another process, which should properly be termed the washing, has for its object the removal from the wool already worked up, combed, spun, or dyed, of foreign matter, grease particularly, with which it may be loaded. The treatment consists of steeping and washing it with lukewarm water, hydrochloric acid, and carbonate of soda.

THE MICA INDUSTRY OF THE UNITED STATES.

The production of cut mica in the United States in 1889 amounted to 49,500 lb., valued at 50,000 dols. In addition to this, 196 short tons of scrap or waste mica were sold for grinding purposes, with a value of 2,450 dols. The production in 1880, as given in the 10th Census Report, was 81,669 lb. of cut mica, valued at 127,825 dols.

A review of the annual production during the past nine years shows that the industry advanced in importance until 1885. Since then the tendency has been downward, though the fluctuations in the production of the different regions have caused much irregularity in the annual totals. The following table does not include statistics of scrap and waste mica, as there had been no attempt prior to 1889 to determine the amount of this waste which has been utilised:—

Years.	Amount.	Value.	Years.	Amount.	Value.
	Lb.	Dols.		Lb.	Dols.
1880	81,669	127,825	1885	92,000	161,000
1881	100,000	250,000	1886	40,000	70,000
1882	100,000	250,000	1887	70,000	142,250
1883	111,000	285,000	1888	48,000	70,000
1884	147,110	308,525	1889	49,500	50,000

During the years 1883 and 1884, when mica mining was in its most flourishing condition, the manufacturers of stoves consumed probably 95 per cent. of the product, and the fancy grades and large sizes of sheet mica which were then used found a ready sale at highly profitable prices. Under this stimulus of large profits many surface deposits or pockets were opened by farmers or other individuals of small means, who worked them occasionally when other business was dull and realised a considerable profit on their production. As long as the demand for large sizes continued this intermittent sort of mining could be carried on with a degree of success, but when the fashion in stove panels changed, and small sheets were used in place of the large ones, the demand for the latter fell off to a great extent. Mica suitable for cutting into large sheets was

much less abundant than that available for small sizes; therefore lower rates had always prevailed for the latter, and careful, steady, and systematic methods were necessary to produce such grades profitably. When the demand changed from large to small sizes the majority of miners were unprepared through lack of capital or for other reasons to adopt such methods. The result was a great reduction in the number of producing mines, and consumers were compelled either to raise the price of mica or look to foreign sources for their supply. Another factor in increasing importation came into existence with the extended manufacture of dynamos and other electrical apparatus, in which a great deal of mica is used. The foreign article, especially that produced in Canada, was, on account of its superior cleavage, preferred to the domestic for this purpose, but since miners have become more fully acquainted with the qualities desired for electrical uses it has been proved that the United States can produce mica for this purpose equal to any found abroad. The foreign supply, after gaining a foothold in American markets, has more than held its own, and as its tendency has always been toward a reduction in prices, there has been little inducement for the outlay of capital in mica mining.

Only a small number of mines were operated in 1889, and a few of these were worked steadily throughout the year. However, there was a fair amount of development work done in the different mica regions, and it is expected that the introduction of more systematic methods of mining will greatly increase the importance of the industry.

Occurrence.—The localities in which mica occurs in an available form are not very numerous, and it is only in New Hampshire and North Carolina that the industry has assumed much importance. In the West the most important deposits are located in the Black Hills, in the neighbourhood of Harteville, Wyo., and in the Cribbensville district of New Mexico.

The available deposits of mica occur in bands of coarsely crystalline granite. In these bands the three constituents of the granite (mica, feldspar, and quartz) have in a measure crystallised in separate masses, and the mica is found in bunches or pockets irregularly distributed throughout the mass. The deposits are of great interest aside from their commercial importance on account of the number of rare minerals which are nearly always present. Among these are beryl, tourmaline, garnet, columbite, and samarskite. In some cases one or more of these minerals are present in sufficient quantity and of such fine quality as to give value to the deposit. Some of the finest tourmalines in the world have been found at Mount Mica, near the town of Paris, Maine, in the mica deposit at that place. Tin ore is also an accompaniment of the mica deposits in the Black Hills region.

Treatment of the Crude Product.—Mica is used in two forms, sheet mica and ground mica, and the manner in which it is treated when taken from the mine depends upon the form in which it is to be used. If it is to be sold as

scrap for grinding, all that is necessary is to remove the adhering fragments of quartz and feldspar and such parts of the mica as may contain foreign ingredients. If it is to be used in the sheet form the process is much more complicated, the blocks being first split into sheets thin enough to cut easily, then marked with a pattern of the size desired, cut along the lines marked, and the different sizes wrapped in paper, and packed for shipment. There is a great amount of waste about this operation. The amount of sheet mica obtained does not usually exceed from 4 per cent. to 8 per cent. of the block mica treated.

Uses.—The most common and well-known use for mica is in the panelling of stove and furnace doors. For this purpose the mica must be clear, free from spots, and of a uniform colour throughout the sheet. The most desirable colour is a wine-red, and next to this comes white mica, which is nearly as valuable. Another important use is in the manufacture of electrical apparatus, for which purpose its non-conducting properties render it valuable. The qualities required for this use are firmness of texture, toughness, and ready cleavage.

There is a greater range of use for ground mica than for the mineral in sheets, and, though the value of that part of the product made use of in this form is small, the many peculiar properties which ground mica possesses render it quite probable that its use will be widely extended. The difficulties to be overcome in grinding mica are considerable, and there are only two or three firms engaged in the business at present. Eight standard grades of ground mica are made. The coarsest of these are used to give frosted and spangled effects to the fancy grades of wall paper. The medium grades are employed in the manufacture of a lubricant for the journals of railway carriages, for heavy bearings generally, and for the axles of road vehicles. The finest grades are used in producing a uniform metallic white surface on wall paper. Scrap mica for grinding must be white and as free from specks or coloured matter as possible, since any impurities in the scrap will affect the colour and lustre of the product.

Production.—The greater part of the product in 1889 was taken from one mine in New Hampshire. Of the North Carolina mines none were in steady operation throughout the year, and the production of that State was the result of irregular and spasmodic efforts. In Virginia the production was confined to one mine, located at Amelia Court House, which was exhausted early in the year. In the Black Hills region, where, in 1884, 11 mines were operated, with a production of over 18,000 lbs. of mica, only one produced in 1889, and that only a small amount. In New Mexico a good deal of development work was done and a quantity of good mica was reported as taken out; but as none of this was marketed it has not been included in the totals for 1889.

The statistics of the industry in 1889 are shown in the following table:—

Distribution.	Production.				Expenses.		Men Employed.	Capital Invested.
	Cut.		Scrap.		Total.	Wages.		
	Pounds.	Value.	Short Tons.	Value.				
		Dols.		Dols.	Dols.	Dols.		Dols.
New Hampshire	40,000	40,000	150	2,000	38,635	28,330	70	191,730
North Carolina	6,700	7,000	12,722	7,206	63	438,475

FIXATION OF NITROGEN BY ELECTRICITY.

M. Berthelot, Director of the Meudon Station of Vegetable Chemistry, reports that experiments carried out during the past season, in continuation of a long series of researches, confirm previous conclusions as to the effect of electricity in facilitating the fixation of nitrogen by the soil and by plants. The operations necessary for obtaining results are too complicated and costly to be employed commercially in agriculture or horticulture; but they are interesting in so far as they show the connexion of electricity with fertility in the ordinary course of nature. The gain of nitrogen where electricity has been employed has been great, not only in soil covered with vegetation, but also in that kept bare, and in the open air as well as in closed receptacles. —*Standard Agricultural Reports.*

REMEDIES FOR POTATO DISEASE.

The annual report of the Intelligence Department of the Board of Agriculture on injurious insects and fungi in 1890, travels of much the same ground as Miss Ormerod's report, previously issued, but it has the advantage of being published by the Queen's Printers at a nominal cost. The most interesting portions of it are those relating to remedies for potato disease, and the use of insecticides for fruit trees. The results of some experiments carried out by the United States Department of Agriculture in the application of *Bouillie bordelaise*, a mixture of sulphate of copper and quicklime, used for the vine mildew in France, are recorded. The details are not satisfactory, because neither the size of the plots (or "plats," as given in the report, American spelling being adopted) nor the total quantity of the mixture used during the season is given. The piece of land was divided into three parts, there being 75 hills of potatoes in each. To two of these plots a mixture consisting of 6 lb. of sulphate of copper, 4 lb. of quicklime, and 22 gallons of water was applied where the plants were a foot high, the application being repeated every fortnight until the 10th of September. The remaining plot was not treated. The results were yields of 346 lb. and 283 lb. on the dressed plots, and 164 lb. on the plot not sprayed. The proportions of the mixture are not the same as those used in France and Belgium, namely, two parts of copper sulphate to one part of lime. M. Petermann, of the Gendboux Agricultural Station, Belgium, has succeeded in reducing the proportion of diseased potatoes from 30 per cent. where no dressing was applied, to 7 per cent. where the mixture was used. He recommends one application, as soon as any signs of disease appear, of 44 lb. of sulphate of copper, 22 lb. of quicklime, and 220 gallons of water per acre, syringed over the potato tops. In the report it is stated that the wash is inexpensive; but it certainly would not be so if applied frequently, as in the American experiment. The quantities just named would cost about 7s. 6d. per acre at the present price of sulphate of copper, which might be doubled if there were any great demand for it, either for vines or potatoes. Mr. Petermann believes that sulphate of iron would do instead of copper sulphate, and this should be tried, as it is much less costly.

As it is probable that many persons will desire to try the remedy for potato disease, a description of the method pursued in preparing the mixture will be useful. The sulphate of copper is placed in a wooden vessel and dissolved in a few gallons of boiling water, the quantity not being material so long as it is measured. In another vessel the quicklime is dissolved by first slaking it, and then adding more water and stirring it well. If any lumps are left undissolved they should be removed and replaced with an equal weight of fresh lime. When both materials are dissolved the lime water is poured into the copper solution through a fine sieve to keep back any pieces of undissolved lime, and then the entire mixture is well stirred, and the rest of the water is added. When being used the mixture should be frequently stirred. It is recommended for hop mildew and onion mildew, as well as for potatoes and vines; but market gardeners may well be warned that it would not be safe to use the poison on onions which are to be pulled in a week or two.

DISCOVERY OF ASBESTOS IN NEW SOUTH WALES.

The *Sydney Morning Herald* of March 16th says:— "Mr. C. S. Wilkinson, the Government geologist, has received from Mr. J. R. Edwards, a solicitor at Broken Hill, several samples of asbestos, which were discovered at Red Hill, near Broken Hill. The asbestos was obtained in a vein measuring from 2½ ft. to 3 ft. in width, at a depth of 10 ft. from the surface. Some of it contains fibre 13 in. long, the texture being silky and flexible. The Broken Hill material is not, however, as strong or tough as the Italian asbestos. The colour, too, is different, as the Broken Hill asbestos is reddish in hue, owing to the influence of iron oxide. It is expected that a white mineral will be found at a greater depth. Several tons of asbestos have been brought to grass."

PAPERS OF INTEREST TO TECHNOLOGISTS AND MANUFACTURERS.

The following articles in the *Board of Trade Journal* for May will repay perusal:—

- "Cost of Production of Piece-Dyed Satins at Lyons," p. 505.
- "French Mining Industries," p. 507.
- "The Wealth and Resources of Alaska," p. 524.

Monthly Patent List.

* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

I.—GENERAL PLANT, APPARATUS, AND
MACHINERY.

APPLICATIONS.

6797. G. Weigelin. See Class VIII.
6798. A. J. Boulton.—From L. Falasconi, Italy. Improvements in kilns for furnaces. April 20.
6887. J. Peake. Improvements in or relating to kilns for various purposes. April 21.
7187. S. M. Lillie. Improvements in evaporating apparatus. Complete Specification. Filed April 25. Date applied for September 26, 1890, being date of application in United States.
7188. M. Merichenski. Improvements in carburettors. April 25.
7205. The Gascons and Liquid Fuel Supply Co., Ltd., and B. H. Thwaite. Improvements in apparatus for inducing the flow of, and injecting and spraying, gaseous and liquid fluids. Complete Specification. April 27.
7216. J. Jones. See Class XVII.
7336. A. J. Boulton.—From G. Castanos and G. L. de Lara, France. Improvements in apparatus for extracting the juice from oily and pulpy substances. April 28.
7464. A. Hof. Improvements in carburating or carbonising apparatus. April 30.
7416. W. Birch. Improved apparatus applicable to the cleansing or filtration of sewage and other liquids. April 30.
7636. T. A. A. Pile and W. A. Pile. Improvements in machines for moulding and pressing clay or other plastic materials. May 2.
7704. H. Burgess and C. D. Davis. Vacuum evaporating apparatus. Complete Specification. May 4.
7725. A. Suiter. Improvements in fittings for compressed gas-vessels. May 5.

7770. A. Bridge and C. A. D. Evans. Improvements in devices for utilising the circulation of hot fluids in washing, dyeing, extracting, concentrating, and other analogous apparatus. May 5.

7867. W. P. Thompson.—From Wirth & Co., Germany. Improvements in evaporating apparatus for concentrating liquids. May 7.

7869. W. P. Thompson.—From Wirth & Co., Germany. Improvements in evaporating apparatus for concentrating liquids of a pulpy nature. May 7.

8047. J. T. Pearson. An improved means or apparatus for humidifying fibrous substances. May 11.

8167. R. D. Gates. Improvements in concentrating apparatus. Complete Specification. May 12.

8169. H. L. Callendar. Improvements in thermometers. May 12.

8177. F. Smith and W. Travis. Improved apparatus for drawing off liquids. May 13.

8475. W. P. Thompson.—From P. Marix, France. Improvements in and relating to the method of effecting by means of centrifugal force the reaction of bodies of different densities on one another. May 16.

COMPLETE SPECIFICATIONS ACCEPTED.*

1890.

1235. R. Mannesmann. Method and apparatus for compressing air or other gaseous fluid. April 29.

1236. R. Mannesmann. Method and apparatus for compressing air or other gaseous fluid. April 29.

10,380. J. Murrie. Improved pyrometers or thermometers. May 20.

10,788. H. M. Saint Denis. Centrifugal drying machines. May 6.

11,042. J. W. Gooch, C. A. Baker, and W. White. Electric thermometers and thermographs. May 20.

11,082. J. Whitehead. Supplying fuel to furnaces and apparatus therefor. May 20.

12,421. D. Bethmont. Apparatus for generating steam, or vaporising liquids. May 20.

12,542. E. Guigon. Circulation of water in surface condensers. May 13.

1891.

3187. A. W. Ellis. Stand for chemical or other purposes. May 13.

3435. E. Nelson. Treating heated liquid wastes, and apparatus therefor. May 20.

3997. C. Smith.—From A. de Kunwald. Apparatus for pumping, forcing, or exhausting liquids or gases. May 6.

5175. S. C. Hauberg. Centrifugal apparatus for testing the composition of milk and other compound of fluids. May 13.

5555. R. Haddan.—From J. W. Evans. Evaporators. May 6.

6405. J. R. Whiting and W. A. Lawrence. Recovery and utilisation of certain vaporised solvents. May 20.

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

6741. C. H. Bolz and A. Lühning. Improvements in the manufacture of illuminating and heating gas. April 20.

6794. F. J. Jones. Improvements in apparatus for washing or scrubbing and purifying gas in gas or coke making. April 20.

6947. W. T. Cotton and E. F. B. Crowther. An improved fire clay (inclined) gas retort with fittings attached to feed and clear the retort. April 22.

7064. A. C. Caddick and Co. Improvements in apparatus for making gas. April 24.

7092. A. A. Lister. Improvements in apparatus for extracting tar and ammonia from gas. April 24.

7202. F. J. Jones. Improvements in the manufacture of coke. April 25.

7558. L. Loewenthal. Improved manufacture or production of gas, and means or apparatus for the storage and application thereof. May 1.

7583. J. D. Bourán. The improvement of coal-gas retorts. May 1.

7648. E. Stauber. Process and appliances for producing peat coke cakes. May 2.

7846. B. Egger. Automatic apparatus for indicating the presence in or absence from a space of gases of different specific gravity from the ordinary gaseous contents of such space. May 6.

7983. A. A. Dixon. Improvements in and in apparatus for the manufacture of crude peat into fuel. Complete Specification. May 9.

8067. T. Keetman and W. Bach. Apparatus for charging and discharging gas retorts and other vessels. Complete Specification. May 11.

8068. T. Keetman and W. Bach. Scoop for discharging gas retorts. Complete Specification. May 11.

8071. C. H. Fitzmaurice. Improved means and appliances for utilising petroleum and the like with steam for heating purposes. May 11.

8176. T. H. Cobley. Improvements in the preparation or manufacture of compressed or block fuel (briquettes), and materials employed therein. May 13.

8413. J. Clegg. Improved means of regulating the preparation of illuminants for incandescent electric lamps. May 15.

8479. J. Ruscoe. Improvements in apparatus for charging and drawing gas retorts. May 16.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

7252. R. C. Lindsay. Manufacture of illuminating gas, and apparatus therefor. April 29.

7739. J. von Langer and L. Cooper. Manufacture of water-gas. May 20.

7830. B. C. Sykes and G. Blamires. Conversion of solid into gaseous fuel, and purifying same. May 6.

8752. W. Cryer. Means for producing or separating oxygen and nitrogen from atmospheric air; applicable for manufacturing other gases. May 6.

8909. H. Woodhall. Apparatus for charging inclined gas retorts. April 29.

8930. L. S. d'Izoro. Apparatus for charging and drawing gas retorts. May 13.

8958. J. Finney. Fire-lighter, and machinery for making same. May 6.

* See Note * on previous page.

9331. J. A. Whitby. The magic fire-lighter. April 29.

10,155. J. Roseoe. Means and appliances for facilitating charging and drawing certain gas retorts. May 13.

11,079. J. Laing. Apparatus for destructive distillation of mineral oils. May 20.

11,106. J. E. Bott, W. Mortimore, and F. H. Lindley. Gas-producers. May 20.

14,052. L. H. Armour. Means for the manufacture of hard coke, distilling shale, washing ores, and similar operations. May 20.

1891.

2145. G. Hargreaves, J. P. Scranton, and E. W. Porter. Apparatus for carburetting air. April 29.

2889. W. P. Thompson.—From G. S. Sandford. Apparatus for the manufacture of gas from petroleum oil. April 29.

1834. A. Lutschauwig. Manufacture of fire-lighter or fire-lighting material. May 13.

IV.—COLOURING MATTERS AND DYES.

APPLICATIONS.

6972. S. Pitt.—From L. Cassella and Co., Germany. Production of amidonaphtholsulpho acids and of dye-stuffs therefrom. April 22.

7258. J. Y. Johnson.—From The Badische Anilin and Soda Fabrik, Germany. Improvements in the manufacture and production of dyes belonging to the rhodamine series, and of new materials for use in their preparation. April 27.

7692. A. Fischesser. An improved process for producing azo-colouring matters and sulpho acid. May 4.

7713. J. Y. Johnson.—From The Badische Anilin and Soda Fabrik, Germany. The manufacture and production of diazo dyes, and of intermediate products in their preparation. May 4.

7803. A. Lembach, F. Schleicher, and C. F. Wolf. Improvements in the manufacture of ortho-oxy-quinoline and oxyquinoline derivatives. Complete Specification. May 6.

7963. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brünig. Manufacture of nitro- and amido-methyl-phenyl-pyrazolon. May 8.

7964. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brünig. Production of blue colouring matters. May 8.

8407. S. Pitt.—From L. Cassella and Co., Germany. Production of blue dyestuffs. May 15.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

8243. W. R. Lake.—From A. Leonhardt and Co. Manufacture of colouring matters. April 29.

8726. J. Y. Johnson.—From The Badische Anilin and Soda Fabrik. Production of a new compound, and of artificial indigo from phenyl-glyceoll or analogous compounds or derivatives thereof. May 13.

9200. R. W. E. MacIvor. Manufacture of ultramarine. May 20.

9676. J. Y. Johnson.—From The Badische Anilin and Soda Fabrik. Manufacture of substantive dyestuffs and of materials therefor. April 29.

9768. J. Dawson and R. Hirsch. Production of a new naphthylendiammonosulpho acid. May 6.

10,095. J. Y. Johnson.—From The Badische Anilin and Soda Fabrik. Manufacture of trioxy-benzo-phenone, a colouring matter of the oxyketone group. May 6.

10,401. W. S. Conrad. An instantaneous copying-ink. May 20.

10,509. J. Y. Johnson.—From The Badische Anilin and Soda Fabrik. Production of artificial indigo, and of a new material for use therein. May 13.

10,599. H. H. Lake.—From K. Ochler. Manufacture of colouring matters. May 6.

11,518. J. Imray.—From La Société Anonyme des Matières Colorantes et Produits Chim. de St. Denis. Manufacture of azo-colouring matters derived from azo-oxyamines. May 20.

V.—TEXTILES, COTTON, WOOL, SILK, Etc.

APPLICATIONS.

7458. S. C. Dhondy. Sizing compounds for cotton yarn. April 30.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

7423. W. Peters. Method and appliances for tarring, colouring, and preparing thread, hemp, jute, &c. for sewing. May 20.

10,285. T. J. Hutchinson. Method and means for removing fatty matters from textile fabrics. May 13.

17,531. R. W. Thom. Backing or back starching and finishing textile fabrics. April 29.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

6862. A. E. J. Mahieu. New or improved process for bleaching thread, yarn, and fabrics of linen, hemp, and other textile materials. April 21.

8064. J. C. F. Guthier. An improved vat-dyeing process. May 11.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

7198. W. H. Spencer. Bleaching textile fibres. May 6.

7786. A. F. S. George. Method and apparatus for producing coloured designs upon and through floor and wall-covering materials. April 29.

7787. A. F. S. George. Colouring and inlaying coloured designs upon and through linoleum and other materials. April 29.

10,323. W. Hutchinson. Apparatus for boiling, scouring, or cleansing textile fabrics. May 13.

11,100. A. H. Wardle. Machinery for dyeing hanks of silk and other yarn. May 20.

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

7362. C. Kellner. Improved apparatus for recovering sulphurous acid used in the manufacture of paper pulp from wood. Complete Specification. April 29.

7437. E. Fleischer. Improvements in and connected with the manufacture of alkali aluminates. April 29.

7654. G. F. Brindley. Improvements in the production of solid compounds of sulphuric acid and acid sulphate of sodium or potassium. May 2.

7757. C. H. Fish. Improvements in furnaces for burning sulphur. Complete Specification. May 5.

7893. J. J. Shedlock and T. Denny. See Class X.

8006. E. L. C. Martin. Improvements in the manufacture of caustic soda and caustic potash. May 9.

8018. G. Lunge and J. Dewar. A process for recovery of sulphur, carbonate of soda, and iron oxide from double sulphide of sodium and iron. May 9.

8293. H. H. Leigh.—From J. Elsner, France, and R. Gasch, Germany. Improvements in process and apparatus for procuring cyanogen and its compounds from gases. May 14.

8344. W. Bowman. — From J. H. Bowman, Canada. Improved process for the treatment of phosphate of alumina, phosphates of alumina and iron, and the like. May 15.

8470. G. Bamberg. Improvements in the manufacture of silicate of soda and carbonate of soda, and in apparatus for that purpose. May 16.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

7247. H. Baudouin and P. F. Escarpit. Process and apparatus for manufacture of ammonia. May 20.

7527. J. Vivian and G. Bell. Apparatus for use in manufacture of bicarbonate of soda by the ammonia process. April 29.

8301. R. H. Davidson and R. H. Davis. Treatment of alkali waste for production of sulphuretted hydrogen. May 13.

9112. F. Ellershausen. Manufacture of caustic soda. May 6.

10,115. H. Precht. Process and apparatus for purifying double carbonate of potassium and magnesium. April 29.

12,717. H. B. Yardley. Utilisation of gases which form insoluble or partially insoluble precipitates. May 20.

1891.

2019. W. Walker. Process and apparatus for obtaining silicates for making glass, and the production of hydrochloric acid. May 13.

VIII.—GLASS, POTTERY, AND EARTHENWARE.

APPLICATIONS.

6797. G. Weigelin. Improvements in the methods and appliances for drying moist material, for instance, newly formed bricks, pipes, flags, and such like, by means of artificial heat. Complete Specification. April 20.

6924. E. Bilton. A method of glazing pottery, porcelain, and similar bodies. April 22.

7040. W. A. Kerr. See Class IX.

7156. J. S. Williams. Decoration on china. April 30.

7547. J. Morton. Improvements in kilns for burning retorts, pipes, quarries, and other refractory substances. May 1.

7773. T. H. Catlow and A. H. Vass. An improved construction of kiln for burning bricks and like goods. May 5.

7826. J. G. Sowerby. Improvements in the formation of glass bottles. May 6.

7885. C. Blount, V. Ward, and A. Fisher. Translucent cloisonne enamel. Complete Specification. May 7.

7896. F. W. Draycott. An improved device for use in supporting pottery ware whilst being fired. May 7.

7908. J. E. Bousfield.—From F. Schultz, Germany. Improvements in the manufacture of stove-tiles, mouldings, rosettes, and the like, and in apparatus therefor. Complete Specification. May 7.

7909. Craven, Dunnill, and Co., Lim., and F. R. Smith. Improvements in the manufacture of tiles, ceramic, mosaic, and the like, and in apparatus therefor. May 7.

7988. T. C. J. Thomas. Improvements in the manufacture of glass. May 9.

7999. H. S. Berge. An improved glass-melting furnace. May 9.

8090. G. Gehring. Improvements in and relating to enamel for metals, glassware, earthenware, and other materials. Complete Specification. May 11.

8221. C. J. Chubb and J. G. Ivey. An improvement in or connected with the manufacture of colourless or light coloured glass, and such like ware. May 13.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

9172. R. J. Withers. Roof and hanging tiles. April 29.

9867. W. H. Hilde. Manufacture of hollow glass-ware, and apparatus therefor. May 13.

9942. O. Dillmann. Producing coloured designs on glass. April 29.

11,279. Gibbons, Hinton, and Co. Manufacture of ornamental tiles. May 20.

12,212. G. F. Chance, and Chance Bros. and Co., Lim. Lears for annealing sheets of glass. May 6.

1891.

2019. W. Walker. See Class VII.

5782. A. J. Boulton.—From L. T. Harras and G. Hoffmann. Manufacture of glass letters and the like. May 13.

6118. H. Warrington. Kilns or ovens for bricks, earthenware, porcelain, and similar material. May 20.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

6937. G. Haynes. An improved combination of materials for paving, coping, and other purposes. April 22.

7040. W. A. Kerr. An improved composition or compound designed to serve as a substitute for wood, and also applicable for the manufacture of bricks and crencibles, retorts, and other articles of earthenware. April 23.

7043. S. Snell. An improved combination of materials for producing ornamental work and mouldings. April 23.

7184. W. W. Horn.—From W. L. Mason, T. W. Blakey, and J. A. Wright, United States. An improved artificial stone. April 25.

7190. E. M. Thomlinson. Improvements in the manufacture of cement. April 25.

7717. F. W. S. Stokes. Improvements in apparatus connected with the continuous treatment of lime, cement, and the like materials, and in the lining of kilns and furnaces for burning basic materials. May 5.

7773. T. H. Catlow and A. H. Vass. An improved construction of kiln for burning bricks and like goods. May 5.

7845. H. Falja. Improvements in continuous or running kilns for the calcination of cement. May 6.

8017. O. Murray.—From F. Zernikow, Germany. Improved apparatus employed in the manufacture of artificial sand-stone. Complete Specification. May 9.

8347. C. Witkowsky. A composition of matter consisting in casein-cement. Complete Specification. May 13.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

8993. V. L. Daguzan. Cementing material. April 29.

10,036. J. P. Bayly.—From W. Lenderoth. Manufacture of porous earthenware building material. May 6.

11,796. F. Dupont. Manufacture of compound slabs of plaster, cement, &c. May 20.

1891.

6118. H. Warrington. See Class VIII.

7676. A. J. Campion. Improvement in the manufacture of pewter, solder, Britannia metal, metal sheathing, and anti-friction and other hard metals. May 4.

7718. J. A. Mays. Improvements in amalgamation, and in amalgamating apparatus. May 5.

7777. W. P. Thompson.—From F. J. Clamer, United States. Improvements in or connected with the cooling of certain metals or metal articles with other metals or alloys. Complete Specification. May 5.

7824. W. Skaife. Improvements in or relating to galvanising metals. May 6.

7893. J. J. Shedlock and T. Denny. Improvements in the process of and apparatus for the treatment of sulphides and other analogous metallic compounds. May 7.

8083. L. Mond. Improvements in manufacturing nickel alloys. May 11.

8111. B. J. B. Mills.—From W. L. Brockway, United States. Improvements in the treatment of waste tinned steel or iron. Complete Specification. May 12.

8122. B. Krantz and H. Zeissler. A method of decorating metal articles with other metals deposited thereon. Complete Specification. May 12.

8127. W. G. Richards. Improvements in process of and moulds for making castings. Complete Specification. May 12.

8137. S. Pearson and J. H. Pratt. New or improved metallic alloys. May 12.

8415. A. W. Warwick. A process for extraction of antimony from its ores, and separation of other metals therefrom. May 15.

8471. W. F. Shand. Improvements in means and apparatus for the manufacture of steel. May 16.

8472. W. F. Shand. Improvements in the manufacture of steel, iron, and other metals. May 16.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

1369. G. C. Fricker. Cleaning and annealing iron and steel, and apparatus therefor. April 29.

7827. S. Fox. Application of water-gas to the manufacture of iron and steel in connexion with Siemens' and other gas-furnaces. May 6.

10,062. J. Bradbury. Utilisation of iron oxide obtained as a by-product in extracting copper from pyrites, or from spent oxide produced in the manufacture of sulphuric acid. April 29.

10,783. A. McDougall. Process for recovering tin from tin-plate, in which zinc-white is produced as a by-product. May 20.

11,606. P. Rogers and J. Player. Apparatus for coating metal sheets, &c., with tin, lead, &c. May 20.

1891.

5107. H. Warrington. Fire grates for puddling, heating, and similar purposes. May 13.

5242. W. B. Binsdale. Process of casting ingots. May 6.

6323. E. Taussig. Apparatus for smelting and casting. May 20.

X.—METALLURGY, MINING, ETC.

APPLICATIONS.

6808. J. Lang and E. H. Wigham. A process for protecting iron and steel against oxidation. April 20.

6844. J. Carlton and J. Reid. Improvements in annealing or treating steel or iron. April 21.

6883. C. T. J. Vautin. Improvements in the recovery of gold from solutions. April 21.

6942. W. Beardmore. Improvements in the manufacture of armour plates, and in apparatus therefor. April 22.

7022. J. O'Neill and J. E. Hartley. Improvements in the process of bronzing metallic surfaces. April 23.

7050. F. M. Lyte and C. H. M. Lyte. An improved method of coating iron and steel with lead. April 23.

7069. J. Willis. Improvements in the manufacture of iron or steel ingot moulds or chills. April 24.

7088. J. C. Butterfield. Improvements in the treatment of bluestone and other sulphurised ores. April 24.

7150. N. Lachédeff. Improvements in the manufacture of iron and steel. April 25.

7585. H. L. Herrenschildt. Improved processes for the treatment of silicated nickel ores and pyritic ores of nickel and copper, or nickel, copper, and cobalt. May 1.

7625. A. Tropenas. Improvements in the manufacture of steel, steel castings, or ingot iron, and in apparatus and appliances employed therein. May 2.

7673. W. C. Morison. Improvements in and connected with the reduction of ores. May 4.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

APPLICATIONS.

6767. W. Lucas and T. A. Garrett. Improved means for the production of ozone electrically. April 20.

6793. P. C. E. Champion. The application of electricity for the production of pyrotechnic and other similar effects, and apparatus therefor. April 20.

7052. W. Boggett. Improved methods of obtaining electricity. April 23.

7168. G. Wester. Improvements in and relating to voltaic cells. Complete Specification. April 25.

7261. E. Dénorus. Improvements in and relating to the electro-deposition of metals upon fabrics, plants, animals, and the like. April 27.

7434. A. Nodon. Improvements in the electrolysis of chlorides, and in the utilisation of the liberated chlorine for the manufacture of chlorates, hypochlorites, and other compounds. April 29.

7697. C. P. Eliason. Improvements in electrical accumulators or storage batteries. May 4.

7700. H. J. Allison.—From P. Kennedy and C. J. Diss, United States. Improvements in storage battery plates. May 4.

7701. H. J. Allison.—From P. Kennedy and C. J. Diss, United States. An improved storage battery plate and method of making same. May 4.

7715. G. A. Washburn. Improvements in storage batteries. Complete Specification. May 5.

7831. H. Reynier. Improvements relating to the manufacture of insulating partitions for use in primary and secondary batteries. May 6.

7949. P. Goward. Improvements in secondary batteries. May 8.

7960. R. D. Sanders. Improvements in apparatus for use in the manufacture of metal tubes, cylinders, or other articles by electro-deposition. May 8.

7979. G. E. B. Pritchett. Improvements in electric accumulators or secondary batteries. May 9.

8126. G. J. Philpott. Improvements in compound dynamo-electric generators. May 12.

8218. A. R. Sennett and F. W. Cannon. Improvements in dry batteries. May 13.

8227. W. P. Thompson.—From H. O. Tudor, Germany. Improvements in electrodes for electric accumulators. May 13.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

8394. W. Wright. Battery compound. May 13.

8716. E. Edwards.—From T. Lange. Obtaining metallic zinc from solution of zinc sulphate by electrical decomposition. April 29.

9257. S. Wohle. Effecting electrolytic deposit with aluminium. May 13.

9991. T. Parker. Manufacture of iron by electrolysis. May 6.

10,038. A. Watt. Electrolytic treatment of metals. May 6.

1891.

3331. S. C. C. Currie. Secondary or storage batteries. May 13.

3799. A. Clark. Improved solution or composition for charging electric batteries. May 13.

5547. C. Kellner. Apparatus for electrolytic decomposition. May 20.

XII.—FATS, OILS, AND SOAP MANUFACTURE.

APPLICATIONS.

6829. J. W. Gardner and T. Smithson. Improvements in the manufacture of toilet soap. April 21.

7251. W. N. Hartley and W. E. B. Blenkinsop. Improvements in the thickening of oil. April 27.

7428. D. T. Gardner.—From M. L. Lichtenstadt, Russia. Improvements connected with the manufacture of soap, and the employment of certain ingredients for that purpose. April 29.

8462. B. Goldmann. Improvements in the manufacture of paint oils and putty oils. May 12.

COMPLETE SPECIFICATION ACCEPTED.

1891.

5870. J. E. A. Bokeland. Preparation for use as a substitute for linseed oil in the mixing of pigments. May 13.

XIII.—PAINTS, PIGMENTS, VARNISHES, AND RESINS.

APPLICATIONS.

6770. D. Everett and T. Claridge. Improvements in the manufacture or production of pigments. April 20.

6810. I. Singer and A. P. Berens. Improved manufacture of white lead, and apparatus therefor. April 20.

6916. T. Maxwell. An improved liquid preparation for the protection of bright or polished or unpolished metallic surfaces, and which may also be used as an anti-fouling and anti-corrosive composition. Complete Specification. April 22.

7036. G. H. Smith. Improvements in the treatment of gums, and the preparation of varnishes therefrom. April 23.

7516. W. K. Breavington. A new and improved powder for the manufacture of ink. April 30.

7798. T. Rowley. Improvements in the process of vulcanising articles or fabrics composed either wholly or partially of india-rubber by what is termed the "dry heat process." May 6.

7848. J. Jeyes. A new or improved compound applicable as gum, size, cement, paint, or varnish, or the like. May 6.

7922. W. L. L. Grant and H. P. T. Dennys. An anti-fouling and preservative paint for protecting the bottoms of iron or wooden vessels, and other submerged surfaces. May 8.

8022. A. Honman and B. Vulliez. Improvements in the process of and apparatus for the manufacture of white lead. May 9.

8161. H. H. Lake.—From F. W. Dahl, United States. Improvements in the manufacture of white lead. Complete Specification. May 12.

8296. A. McLean, jun. Improvements in transparent coloured materials for decorative purposes. May 14.

8311. G. K. Chambers, A. F. Hodgson, and R. Hammond. Improvements in the manufacture of white lead. May 14.

8312. J. A. Egestorff. The manufacture of a paste blue for washing and industrial purposes. May 14.

8480. F. Ragon. An improved manufacture of material applicable as a blacking and for other purposes. May 16.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

8668. B. Piffard. Manufacture of varnishes. May 6.
 16,757. T. W. Just, R. Weiler, and O. Heideprism. Improved ink. May 6.

XIV.—TANNING, LEATHER, GLUE, AND SIZE.

APPLICATIONS.

6852. E. Drew. An improved substitute for leather. Complete Specification. April 21.
 7106. A. Huillard. An improved process of decolourising and clarifying tanning liquors or tannic extracts. April 21.
 7548. J. W. Whinyates. Improvements in the manufacture of leather from hides and skins. May 1.
 7734. A. A. Hunting. Improvements in apparatus for treating or preparing leather. Complete Specification. May 5.
 8096. C. S. Hull and P. S. Burns. Improvements in the treatment of skins and hides. Complete Specification. May 12.

COMPLETE SPECIFICATIONS ACCEPTED.

1891.

2808. W. Barton. See Class V.

XV.—AGRICULTURE AND MANURES.

APPLICATIONS.

8154. F. W. Saatmann. Improvements in the manufacture of superphosphates. May 12.
 8402. A. Knorre. Improvements in the manufacture of artificial manure. May 15.

XVI.—SUGARS, STARCHES, GUMS, Etc.

APPLICATION.

7272. W. P. Thomson.—From A. H. Jacques, Belgium. Improvements in and apparatus for converting amylaceous substances into soluble products. April 27.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

- 11,473. J. Dunann. Treating molasses or syrup to improve its flavour. May 20.

1891.

584. H. H. Leigh.—From W. V. Fry. Process for the defecation of sugar-cane juice. May 20.

XVII.—BREWING, WINES, SPIRITS, Etc.

APPLICATIONS.

7140. S. Mason, jun. Improvements in the method of and apparatus for purifying and refining alcoholic liquors and other fluids. Complete Specification. April 25.
 7216. J. Jones. Improvements in apparatus for mixing, rousing, aerating, and fermenting malt and other liquors. April 27.
 8302. A. Bandholtz. A new or improved apparatus for the direct production of alcohol from mash. May 14.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

7268. W. Dawson. Improvements in distillers' safes, applicable for cheek sampling spent wash at outlets of "patent" stills. April 29.
 8850. E. J. Taylor. Manufacture of whisky and other spirits. April 29.
 9183. C. R. C. Tielhorne, A. E. Durley, M. F. Purell, and S. Geoghegan. Method and appliances for collecting and utilising the carbonic acid gas and other products given off during fermentation. May 13.
 9442. L. C. Best. Apparatus to facilitate the bluing of beer. May 20.
 9940. D. A. Boulanger and A. Scheunert. Process and apparatus for purifying alcoholic liquors. May 6.
 10,436. W. P. Thompson.—From T. Bolland. Distilling apparatus. May 13.

1891.

2294. H. H. Lake.—From G. Guignard and A. Hedouin. Manufacture of alcohol, and apparatus therefor. April 29.
 5004. J. Mitchell. Apparatus for drying distillers' or brewers' draff or dreg, also applicable for drying other similar materials. April 29.
 6317. M. Schwab. Method and apparatus for regulating the egress of spent liquor from distillatory apparatus. May 20.

XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, AND DISINFECTANTS.

APPLICATIONS.

A.—Chemistry of Foods.

7335. W. P. Thomson.—From F. Lanhoff. Improvements in the preparation or treatment of rice or other cereals. Complete Specification. April 28.
 7340. N. Browne.—From L. Nagaele, Belgium. Improvements in the manufacture of bread, and materials employed therein. April 28.
 7345. R. Rick and O. Dahm. A process for the manufacture of artificial "human milk," and other easily digestible foods. April 28.

7485. H. Warry. Improvements in food preservation. Complete Specification. April 30.

8483. D. J. Fereire. New method of preserving organic substances; also applicable for disinfecting purposes. Filed May 16. Date applied for April 20, being date of application in Germany.

B.—Sanitary Chemistry.

7466. W. Birch. See Class I.

7554. G. Knowles and W. H. Cave. A new or improved method of treating vitiated or other air. May 1.

8084. H. Lockwood. Improvements in or connected with the treatment or purification of sewage or other liquids. May 11.

8271. H. Whitley. Improved destructor furnace for refuse, and apparatus connected therewith. May 14.

8426. W. Birch. Improved apparatus applicable to the cleansing or filtration of sewage and other liquids. May 16.

8496. J. Price. Improvements in the treatment of sewage. May 16.

COMPLETE SPECIFICATIONS ACCEPTED.

A.—Chemistry of Foods.

1890.

8804. W. H. Gover. Improvements in and connected with the manufacture of substances of food. May 13.

10,563. F. A. Raetler. Sterilising milk. May 13.

1891.

4291. W. Robertson. Article of food or solidified malt extract jelly. May 20.

B.—Sanitary Chemistry.

1890.

6397. F. B. Hill. Treatment of sewage, and apparatus therefor. April 29.

7419. W. Walkington. Refuse destructor. May 13.

11,048. T. Douglas. Removing gases from sewers, and disinfecting and disposing of them. May 20.

C.—Disinfectants.

1890.

8997. G. Walker. Preparation of disinfectants for more convenient carriage, storage, and general application. April 29.

9103. J. V. Johnson.—From F. von Heyden. Manufacture of disinfectants or antiseptics. May 13.

XIX.—PAPER, PASTEBOARD, Etc.

APPLICATIONS.

6981. W. W. Horn.—From H. Cunningham and S. McDonald, United States. An improved roofing paper. April 22.

7985. E. F. Fleet. Improvements in the manufacture of paper and the like. May 9.

8394. W. Reissig. Improvements in the manufacture of white washable writing tablets. May 15.

8487. A. Sheldon. Improvements in apparatus for the manufacture of paper pulp. May 16.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

9958. A. Gray. Manufacture of a new material, to be called "lacrepap." May 6.

10,259. J. F. N. B. Simons and S. Smith. Manufacture of paper pulp. May 6.

15,776. F. Hawke. Manufacture of copying paper. May 13.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

APPLICATIONS.

6786. J. V. Johnson.—From The Badische Anilin and Soda Fabrik, Germany. Improvements in and relating to the manufacture of hydrazine or diamidogen and its salts. April 20.

7026. B. Willcox.—From The Farbenfabriken vormals F. Bayer and Co., Germany. Improvements in the manufacture of iodine substitution products of phenols and cresols. April 23.

7282. W. H. Claus. A new and improved process for the manufacture of pyrogallie acid. April 28.

COMPLETE SPECIFICATION ACCEPTED.

1891.

48. G. Link and R. Avenarius. Manufacture of artificial perfumes. May 6.

XXI.—PHOTOGRAPHIC PROCESSES AND MATERIALS.

APPLICATIONS.

6762. F. Schraivogel and M. Hering. Proceeding and apparatus of half-tint decomposition for the production of photographic netting plates of half-tint in hatching and grain for clichés of high and low pressure. April 20.

7312. W. W. J. Nicol. Improvements in photographic printing processes. April 28.

7376. B. Krantz and H. Zeissler. Improved apparatus for printing, developing, and finishing photographic prints. April 29.

7635. E. Haackh. Improvements in magnesium lights for photographic and signalling purposes. Complete Specification. May 2.

7785. B. Krantz and H. Zeissler. Method of and apparatus for reproducing photographs. Complete Specification. May 5.

8401. C. N. Staniland and C. J. Staniland. Improvements relating to electro-photography and to electro-photographic apparatus; applicable also to the preparation of printing surfaces. May 15.

XXII.—EXPLOSIVES, MATCHES, Etc.

APPLICATIONS.

7087. H. Schlund. Improvements in distance fuses. April 24.

7193. J. Y. Johnson—From J. A. C. de Latouche, France. Improvements in military and sporting ammunition. April 25.

7256. V. Alder. Improvements in or connected with the manufacture of priming caps or exploders. April 27.

COMPLETE SPECIFICATIONS ACCEPTED.

1890.

5376. H. de Chardonnet. Nitration and denitration of cellulose, regaining the acids employed; and apparatus therefor. April 8.

10,263. K. R. Malstrom. Percussion fuses. May 6.

XXIII.—ANALYTICAL CHEMISTRY.

COMPLETE SPECIFICATION ACCEPTED.

1891.

5175. S. C. Hauberg. See Class I.

NOTICES.

In accordance with the provisions of Rule 18 of the Bye-laws, notice is hereby given that those Members of Council whose names are placed in italics in the annexed list will retire from their respective offices at the forthcoming Annual General Meeting.

Professor J. Emerson Reynolds, F.R.S., has been nominated to the office of President; and Mr. E. Rider Cook has been nominated Vice-President under Rule 11.

Dr. John Evans, F.R.S., Mr. A. Norman Tate, and Sir John Turney, have been nominated Vice-Presidents under Rule 8.

The Treasurer and Foreign Secretary have been nominated for re-election.

Messrs. Arthur Boake, John Christie, Wm. Crowder, Charles Dreyfus, Boverton Redwood, and Wm. Thorp have been nominated, under Rule 18, to fill four vacancies among the Ordinary Members of Council.

ANNUAL GENERAL MEETING.

OUTLINE PROGRAMME.

For selection of Proceedings and Excursions Members may wish to attend.

Tuesday, July 7th.

The Reception Room, Entrance Hall, Trinity College, will be open from 3 p.m. and on succeeding days of Meeting from 10 a.m. Tickets for the selected and necessarily limited Excursions, &c., will here await Members on arrival.

Wednesday, July 8th.

11.0 a.m.—Annual Meeting, Examination Hall, Trinity College.

1.0 p.m.—Luncheon by invitation of the Reception Committee.

2.30 p.m.—Excursion by Steamer in Dublin Bay.

Or—Excursion to Bray, County Wicklow, 3 p.m.

8.0 p.m.—Conversazione by invitation of the Reception Committee.

Thursday, July 9th.

10.30 a.m.—Parties will leave the Reception Room and proceed by Train Car from College Green to Messrs. Power & Son's Distillery, John's Lane, and thence to Messrs. A. Guinness, Son, & Co.'s Brewery, by invitation of the Firms.

Or—Inchicore Railway Works, 10.30 a.m.

4.0 p.m.—Garden Party, if possible.

7.0 for 7.30 p.m.—Annual Dinner.

Note.—From 2 to 4 o'clock on Wednesday and Thursday the following can be visited:—

Factories, &c.—United Alkali Co., Messrs. Goulding's Manure, Alliance Gas Co., Poplin Weaving, Whiskey Distillery Cos., Messrs. Johnston & Co.'s and Boland's Bakeries, Mineral Water, &c.

Other Places of Interest.—Library, Trinity College, National Library, Science and Art Museum, Bank of Ireland (Old Irish Parliament House), National Art Gallery, St. Patrick's and Christ Church Cathedrals, Dunsink Observatory, Zoological Gardens, Phoenix Park, Royal Dublin Society's Buildings, Ball's Bridge, College of Science, Botanic Gardens, Royal Irish Academy.

Friday, July 10th.

Excursion to City Waterworks at Roundwood, County Wicklow, probably returning by Glendalough and Seven Churches.

Or—Excursion to Enniskerry, Dargle, and Waterfall in Powerscourt Demesne, County Wicklow, by permission of the Right Hon. Viscount Powerscourt, K.P.

For particulars relating to above, see detailed Programme, which will be presented to Members on their arrival in Dublin.

Members desiring to extend their visit either North to Belfast and Giant's Causeway, or South to Limerick, Cork, and Killarney, on Saturday, can obtain all necessary information from railway and other agents at the Reception Room.

Tickets of membership will be found with the Ballot Lists in this number of the Journal.

Tickets will be provided for ladies for the Conversazione and Excursions and may be obtained on arrival in Dublin at the Reception Room, Entrance Hall, Trinity College.

Members who intend being present at the Dublin Meeting, and who have not already done so, are particularly requested to fill up and forward at once to the Hon. Secretaries, 35, Dawson Street, Dublin, the form of Outline Programme sent out in the last issue of the Journal.

It is suggested that Members wishing to prolong their stay in Ireland and visit other localities should make enquiries at their respective starting points as to whether by booking via Dublin to the further places they wish to proceed to, the advantage of reduced excursion fares may be secured.

Arrangements can be made in Dublin by which return tickets at reduced fares can be obtained by small parties who may desire to make independent excursions from Dublin.

Post Office Orders should be made payable at the General Post Office, London, to the Honorary Treasurer, E. Rider Cook, and should be forwarded to him at Bow, unless it be desired to notify a change of address.

Members who require extra sets or back numbers of the Journal are requested to make application to the General Secretary only, to whom also changes of address should be communicated.

Notice is hereby given, for the information of members and advertisers, that the advertisement columns of this Journal have been contracted for by Messrs. EYRE and SPOTTISWOODE, the Society's printers and publishers, to whom all communications respecting them should be addressed.

The Secretary is instructed to negotiate for the purchase of copies of the Society's Journal for January and May 1883, and January, February, and April 1886. Members possessing odd copies of these numbers are particularly requested to communicate at once, stating price required, with Mr. Cresswell. The stock of all other numbers is at present sufficient for the Council's requirements.

LIST OF MEMBERS ELECTED, 23rd JUNE, 1891.

Ballinger, John, Free Library, Cardiff, librarian.

Dunwoody, R. G., 369, Calhoun Street, Atlanta, Georgia, U.S.A., chemist.

Ellis, Wm. Hodgson, School of Practical Science, Toronto, Canada, professor of applied chemistry.

Fletcher, R. Jacques, 7, Earl Street, Finsbury, E.C., manufacturing chemist.

Fraser, Leslie McG., 98, Commercial Road East, London, E., chemical engineer.

Kressel, Edw., 41, Park Avenue, Wood Green, N., technical chemist.

Molincux, Roland, c/o C. T. Reynolds & Co., 106, Fulton Street, New York, U.S.A., paintworks chemist.

Mond, Robt. L., 20, Avenue Road, Regent's Park, N.W., chemist.

Nilson, Wm., 3, Beckton Road, Canning Town, E., technical chemist.

Neman, Howard S., P.O. Box 35, Albany, N.Y., U.S.A., dyeworks chemist.

Parkinson, J. Howarth, Stretford, Manchester, gas condenser.

Post, Major Jas. C., 423, Victoria Street, London, S.W., United States Military Attaché.

Sach, Robert, 81, Kelfert Road, Brixton, S.W., mining engineer and assayer.

Scott, Chas. K., Caixa 32, Pernaubuco, Brazil, analytical chemist.

Smith, Francis P., cor. 21st Street and Avenue C, New York, U.S.A., chemist, Consolidated Gasworks.

Stephenson, Claud, 25, Cecil Street, Greenheys, Manchester, Saccharum Co.'s agent.

Stewart, Jeffrey, 15, Claremont Road, Forest Gate, Essex, sugar refinery manager.

Woolcombe, Dr. R. L., 14, Waterloo Road, Dublin, barrister-at-law.

CHANGES OF ADDRESS.

Ballard, E. G., 1/o Eversley Park; 20, Curzon Park, Chester.

Briggs, T. Lynton, 1/o Rodney Street; 357, Madison Street, Brooklyn, N.Y., U.S.A.

Corbould, W. H., 1/o Sydney; Central Broken Hill Silver Mine, Broken Hill, N.S.W.

Crichton, D. G., 1/o Sydney; Central Broken Hill Silver Mine, Broken Hill, N.S.W.

Davis, Dr. P. H., Journals to 106, Saleott Road, Clapham, S.W.

Deering, W. H. (incorrectly described in May No. as 1/o Woolwich), Journals to 13, Hervey Road, Blackheath, S.E.; Woolwich address as before.

Dukes, T. Wm., Journals to c/o Dukes Bros., Caledon and Primrose Streets, Cape Town, S.A.

Hall, R. E., Journals to Box 12, Johannesburg, S.A.R.

Harrison, J., 1/o Gardiner's Hill; 2, Temple Place, Ballintemple, Cork.

Hunt, Bertram, 1/o Leeds; 5, Queen's Crescent, Glasgow. Isherwood, O., 1/o Salford; 36, Walkden Road, near Bolton-le-Moors.

James, Dr. J. Wm., Journals to 29, Redcliff Street, Bristol.

MacIvor, R. W. E., 1/o Clapham Road; 85, Gracechurch Street, London, E.C.

Munro, Professor J. M. H., Journals to Churchfields, Salisbury.

Reid, W. Hamilton, Journals to 22, Shaftesbury Street, Stockton-on-Tees.

Richardson, C. T., 1/o Jarrow; 18, Eldon Street, Newcastle-on-Tyne.

Sadtler, Dr. S. P., 1/o University of Pennsylvania; 145, N. 10th Street, Philadelphia, Pa., U.S.A.

Shaw, Jno., Journals to Earlston, Uddingston, N.B. (net near Edinburgh).

Smiles, Jas., 1/o Brandon Terrace; 19, Queen Street, Edinburgh.

Sowerby, W. M., 1/o Jarrow; c/o United Alkali Co., Limited, Runcorn Works, Cheshire.

Stead, W. H., Journals to Orchard Place, Blackwall, E.

Stevens, W. J., Journals to 24, New Walls Road, Tottenham, Bristol.

Stone, F. B., 1/o Norfolk Villa; Eardley Villa, Picardy Hill, Belvidere, Kent.

CHANGE OF ADDRESS REQUIRED.

Leese, J., 1/o Fylde Road Mill, Preston.

London Section.

CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE.

Chairman: T. Tyrer.

Committee:

W. Crowder.

J. Dewar.

A. G. Green.

S. Hall.

C. W. Heaton.

D. Howard.

C. C. Hutchinson.

R. Messel.

B. E. R. Newlands.

Hon. Local Sec. and Treasurer:

T. W. B. Mumford, 1, Glendale Villas, Sylran Road, Wanstead, E.

The names in italics are those of members of Committee who retire at the end of the current Session.

The following have been elected to fill the vacancies, and will take office in July next:—Committee: C. F. Cross, J. Heron, W. Kellner, G. N. Stoker, and F. Nanier Sutton.

Meeting held Monday, May 14th, 1891.

MR. THOS. TYRER IN THE CHAIR.

THE TREATMENT OF HARD WATER.

By L. ARCHBUTT, F.I.C., AND R. M. DEELEY, M.I.MECH.E.

It is just 50 years since Clark patented his well-known process for the softening of hard water. The kind of hard water with which he proposed to deal is that of which the hardness is due mainly to the presence of carbonates, and which can be softened by the use of lime alone. It appears that Clark did not invent the process of softening water by lime. According to the late Dr. Angus Smith (Report to the Local Govt. Board, 1882), the use of lime was first proposed about a century ago by Thomas Henry, F.R.S., of Manchester. It has also been pointed out by Prosser (Chem. News, 52, 300) that the action of lime in softening water was referred to in a patent taken out by John Melville three years before the date of Clark's patent, and that Melville describes the action of lime as "well-known" in his time. According to this, the softening of hard water by lime was Henry's idea, and by Clark's process should be understood the means of adjusting the proper proportion of lime, consisting in the determination of alkalinity by a standard solution of oxalic acid, the detection of traces of free caustic alkali by the silver test, and the estimation of hardness by the soap test. On the other hand, the process of filtration for the removal of the precipitate was mentioned by Clark in his specification, though he did not indicate any method of filtering. Porter seems to have been the first to patent a filter for the purpose, and he made the softening process a continuous one, the lime water and the hard water being made to flow in regulated streams into a mixing vessel, and thence through filter presses into the storage tank. Atkins, subsequently to Porter, devised an arrangement of plant differing in the construction of the filters and in some other important details; and since then other, and presumably more perfect, filtering arrangements have been devised. So far as we are aware, these filtering arrangements have been limited, at any rate mainly, to the carrying out of the softening process as described by Clark, i.e., to the removal from hard water of the temporary hardness alone; and from statements which have been published, it does not appear that filtration has been uniformly successful in the treatment of waters which have contained magnesium salts.

The alternative method mentioned by Clark, allowing the softened water to clarify by subsidence, has been considered in most places out of the question, because the process in

its simplest form is so slow that very large and costly tanks are required. Gaillot and Huot, proceeding upon the principle that a shallow stratum of turbid water will clarify by gravitation more rapidly than a deep one, have, within the last few years, invented a form of apparatus in which the continuous system of softening has been retained, but the ordinary transmission filter has been superseded by a gravitation filter. Several modifications of the Gaillot and Huot plant have been invented. The chemical treatment adopted with this system of filtration extends to the removal of both temporary and permanent hardness; and the character of the precipitate is immaterial so long as it will settle upon the plates. But, of course, the apparatus is more complicated and more costly than plain tanks of equal capacity would be.

There is still another way of insuring a more rapid clarification of the softened water. It is to use a reagent which shall produce a coarse-grained precipitate which settles quickly; and there is no objection to this provided it does not involve the use of a too costly reagent such as sodium phosphate.

Whatever method of softening water becomes extensively adopted in the long run, it is certain that it must combine the use of the cheapest chemicals with the simplest and cheapest plant. It must also be applicable to all kinds of water, and the softened water produced by the process must be fitted in every respect for the purpose for which it is

intended to be used. The process which will now be described is an attempt towards the realisation of all these conditions. We do not claim that it meets them all perfectly, but we do think the results obtained are of sufficient interest and importance to warrant us in bringing them before the Society. In our process, as in the simplest form of Clark's, the softening and clarification of the hard water are carried out in plain tanks; but owing to the rapid method we use for mixing the chemicals with the water, and the subsequent treatment which the water undergoes, the precipitate is caused to settle very quickly, and only comparatively small cast-iron tanks, such as the diagram represents, are required. Two of these tanks have been in use experimentally in the locomotive works of the Midland Railway Company at Derby for some time past, and another is now being put down by Mr. Johnson. The two experimental tanks have only been softening on an average about 20,000 gallons per day, but from the results obtained it is certain that with the three tanks, each 9 ft. high, and covering a space of 60 ft. x 24 ft. in all, it will be possible to treat 5 million gallons of hard water pumped from the River Derwent per week of 144 hours. These anticipations, based upon what is being done at the present time, are not likely to prove incorrect, for no filters are used, and there is no part of the apparatus which can give trouble when the plant is working to its full capacity. As an illustration of the important effect, the rapidity with which we are able to turn

SOFTENING AND SETTLING TANK.

Elevation.

Plan.

over the water has had upon the dimensions of the tanks required, we may recall the evidence of Mr. Homersham before the Royal Commission on Water Supply, in which he stated that at the Plumstead works, where 1 million gallons of hard water were softened per day, they had, in addition to smaller tanks, three large settling tanks, each capable of holding from 250,000 to 260,000 gallons. For treating 850,000 gallons per day our tanks are just one-tenth the size. Mr. Homersham also stated, with reference to Clark's process, that "it is essential for the process that it should be a clear spring water; a river water is not adapted for being softened by the process." Now, the water we are treating is a river water, which receives the sewage of Derby as well as the refuse of a number of works, before it is pumped into our softening tanks; yet we succeed in properly softening it and in causing a very rapid subsidence of the precipitate produced in the process, besides improving the quality of the water in other ways.

Referring now to the diagram, which represents one of our tanks, you will observe a piece of angle iron, A', fixed to one side of the tank, at a short distance from the bottom, below which the softened water is not pumped out; each operation is therefore commenced with the mud from previous softening at the bottom of the tank, and clear softened water above this as far as the lower angle iron. The *modus operandi* is as follows: The tank is first of all filled with hard water as far as the upper angle iron, A', 20,000 gallons. While this is going on, the proper quantities of chemicals are weighed out and boiled up with a few gallons of water in the small chemical tank, C, and when the large tank is filled, the prepared liquid is caused to flow, by opening the tap, into the well, W, fixed to the middle of one side of the large tank. This well is constructed of ordinary tank plates bolted together, and is freely open to the water in the large tank at the sides and at the bottom. Near the bottom, opposite a pipe which projects into the tank, there is fixed a steam "trajector," T, for the purpose of creating a powerful current of water from the well, through the projecting pipe, into the tank. The action of the trajector would speedily empty the well were it not open at the sides and bottom; as it is, the well fills as rapidly as it empties, and thus a circulation of the water in the tank is set up, and the chemical reagents are very soon thoroughly mixed with the water. The reagents used for the Derwent water consist of lime and sodium carbonate, with crystallised aluminium sulphate in the proportion of 1½ oz. per 1,000 gallons. Good results have lately been obtained, at less cost, with ferrous sulphate. After the admixture of the chemicals and the hard water is complete, which is the case in about five minutes, a test is made with silver nitrate, and if the proper reaction is not obtained, 2 lb. or 3 lb. more lime are slaked, and the milk is run into the well. When the mixing is finished, the trajector is put out of action. The clarification of the softened water is effected by subsidence; but if the turbid water were to be left as it is after turning off the trajector, the process of clarification would take a long time. Some assistance is derived from the aluminium or iron salt used; at any rate, we cannot get such good results without it at Derby, owing to the organic impurity in the water. But what we have found remarkably effectual in promoting the rapid subsidence of the precipitate is to stir up some of the old mud from the bottom of the tank, and diffuse it through the water. In order more completely to effect this than can the trajector alone, perforated pipes, P, are laid along the bottom of the tank, a few feet apart, and, by admitting steam to the blower, B, air is sucked down the orifice and forced out of the perforations in the pipes. The bubbles of air in rising set up currents, which carry up some of the mud, and when sufficient stirring has been effected, the blower is put out of action. The result of this operation is, that the precipitate settles rapidly, and the water becomes so clear in 30 minutes from the time of stopping the air current, that at a depth of 6 ft. from the surface the amount of suspended matter in the water does not exceed on an average about 1 grain per gallon—a quantity of such little importance where the water is required for steam boilers that the drawing off of the softened water may be at once commenced, while another tank is being filled and softened. One arrangement for

drawing off the softened water rapidly without disturbing the sediment is shown at the right-hand end of the tank. The lever, L, closes the opening while softening and settling are going on. If more perfect clarification should be required, or if it were desirable to increase the output of a given plant, a floating orifice can be used. We find, however, that very little is gained in this way, as the great bulk of the precipitate goes down bodily.

With this arrangement, 20,000 gallons of water in one of these tanks is almost as completely under control as a pint of water in a beaker in the laboratory. The appliance for mixing is cheap and effective, and cannot get out of order, and each tankful of water may be treated with just whatever proportions and kind of chemicals we please, and the proper mixing of them with every drop of water is ensured. This is a very important, but not the only, advantage which the intermittent system of softening has over the continuous system. It may be thought that the process will be costly in labour. Extra labour would be necessary for the carrying on of even a continuous process dealing with such large volumes of water, and as a matter of fact the labour involved in our process is quite light, and consists largely in turning valves on and off. The weighing and mixing of chemicals will only occupy a few minutes every hour, so that one man and a lad will easily do all that is required, and the total cost of labour, including interest on the capital outlay, will not amount at Derby to one farthing per 1,000 gallons. This will be in addition to the cost of chemicals, which would of course be incurred by any process. There is also this advantage in our plant, that the cheapest chemicals, lime and sodium carbonate, can be used. Owing probably to the fact that some forms of plant are not adapted to use milk of lime, and that inconveniently large volumes of lime-water would have to be employed, it is the practice to use caustic soda for softening water, and unnecessary expense is incurred thereby, as well as, in some instances, a great waste of chemicals. We know a case where the softened water contained no less than 29.9 grains per gallon of sodium carbonate, as well as 4 grains per gallon of caustic soda.

Practically the softening of all waters is included by the four following equations, since nitrates and chlorides are treated like sulphates:—

To use 2 NaOH instead of Ca(OH)₂ + Na₂CO₃ in equation (4) will cost more, in the proportion of about 100 : 73, if the NaOH is purchased as such. In our process it can be made, if desired, by simply boiling together the Ca(OH)₂ and Na₂CO₃ in the chemical tank, the CaCO₃ + 2 NaOH being run out as a milk into the hard water.

The water which we are softening at Derby gave the following results soon after the process was commenced:—

Grains per Gall.	
Calcium carbonate	9.74
Calcium sulphate	5.64
Magnesium carbonate	2.45
Magnesium sulphate	1.35
Sodium sulphate	3.41
Sodium chloride	2.81
Silica	0.34
	25.74
Calculated hardness	17.9

Containing:
CaO = 7.78 grains.
Containing:
MgO = 1.62 grains.

The softened water, analysed at the same time, gave the following results:—

Grains per Gall.	
Calcium carbonate.....	2.25
Magnesium carbonate.....	2.18
Sodium carbonate.....	0.85
Sodium sulphate.....	11.55
Sodium chloride.....	3.48
Silica.....	0.48
	20.47
Calculated hardness.....	1.78

Better results have been obtained since, as the following partial analyses show:—

Grains per Gallon.							
						A.	B.
Lime (CaO).....	0.78	0.83	0.82	1.32	1.20	2.00	1.37
Magnesia (MgO)....	0.76	0.64	0.66	0.69	0.62	0.51	0.51
Calculated hardness.	3.5	3.1	3.1	4.12	3.7	4.8	3.69

A. This analysis was made on the softened water after settling 30 minutes, and includes the CaCO_3 in suspension.
B. This analysis was another portion of sample A, after standing all night and then filtering.

The water before softening has a dirty brown colour in the tanks; after softening it becomes a deep green. An organic analysis made a few days ago shows how impure the water is when we get it, and also that the treatment which the water undergoes in the process of softening and clarification has the effect of purifying it to a large extent organically also.

	Water from the Mains delivered into the Tanks.	The same Water after Treatment and 30 Minutes subsidence.
Free ammonia.....	1.15 per million	1.08 per million
Albuminoid ammonia.....	0.42 per million	0.28 per million
Oxygen $\frac{1}{2}$ in 45 mins. at 80° F.	0.112 per 70,000	0.059 per 70,000
Absorbed $\frac{1}{2}$ in 4 hours at 80° F.	0.204 per 70,000	0.106 per 70,000

The rapidity with which the precipitate settles in our tanks is due to a combination of causes, of which the stirring up of the precipitate produced in former operations is the most important. It is, however, difficult to determine the precise effect due to this cause alone. Something is gained by the use of the small quantity of aluminium or iron salt, something by the condition of the chemical solution: the circulation kept up by the trajectory and the mere agitation caused by the blower are probably not without their effect. In addition to these comes the effect produced by the mud which the blower brings up from the bottom, the coarse particles of which attract and carry down with them the fine particles of precipitate. Some experiments made in February 1890 show the results obtained by operating in different ways.

In series A and B, the aluminium sulphate was dissolved in a small quantity of water and run into the well by itself; 10 minutes later the lime was added as a milk, and 10 minutes later still the sodium carbonate solution was added. The trajectory was used to mix these solutions with the hard water in both cases, but only in series B was the blower used to stir the mud. In series C and D the chemicals were boiled up together, and the milk was afterwards run out into the well, the trajectory being used to mix the contents of the large tank in both series, but only in series D was the mud stirred by the blower.

Average 8.17	Average 1.06	Average 4.76	Average 1.26

The fact that we are operating upon so filthy a water, the organic impurity of which no doubt varies from day to day, may account for the variations in these results. Judging by the better results which we obtain when the water is at its cleanest, as compared with those obtained at other times, it may be safely asserted that when operating upon a clean well water more perfect average clarification would result. The hard water pumped into our tanks itself always contains suspended matter, and we deliver it with no more, often with less, and sometimes with considerably less suspended matter than we get it. Moreover, the traces of suspended matter in the softened water, after settling for half an hour, consist of nearly pure CaCO_3 , and would admit of very easy separation by the ordinary sand or any other kind of filters if a perfectly bright water were required.

The advantage gained by stirring up the mud with the blower is well shown if we ascertain how long the water takes to clarify to an equal extent without effecting this disturbance. Only two experiments were made in this way, the chemicals being added separately, and the trajectory used for mixing. The suspended matter at a depth of 6 ft. was:—

	Grains per Gallon.
At the end of 1 hour's subsidence.....	6.02
At the end of 2 hours' subsidence.....	1.20
At the end of 3 hours' subsidence.....	3.22
At the end of 4 hours' subsidence.....	2.24
At the end of 5 hours' subsidence.....	1.75
At the end of 6 hours' subsidence.....	1.47

In the second experiment there remained 2.10 grains at the end of 6 hours' subsidence. These figures must be compared with an average of about 1 grain at the end of 30 minutes' subsidence by our complete process.

The mud which accumulates at the bottom of the tanks is very easily removed. When it has reached about half-way up to the lower angle iron, it is stirred up with ordinary brooms, and in this condition it flows through openings, M, in the sides of the tanks into a brick trough which conveys it into the drain. As much as is retained by the flanges of the bottom tank plates is required to carry on the clarifying process.

The water treated by the experimental plant at Derby has, up to the present time, been used for the supply of a small battery of four stationary boilers of locomotive type which provide steam for one of the shops. These boilers had previously been supplied with hard water, and the first effect of the softened water was, as is always the case, to cause the old scale to begin to loosen and fall off. The boilers are now in excellent condition. On the copper fire-box plates and tubes there is practically no scale. The copper stays are coated with a soft deposit, easily rubbed

off, and not thick enough to hide the screw threads. On the iron outer shell the old scale still remains in places, but it is soft and loose, and portions of it which fall off are removed every time the boilers are washed out, which is done once a month instead of once a week as formerly.

Several months after the softening process had been in operation, when the improved condition of the boilers was such that the desirability of extending the process beyond the experimental stage was about to be considered by the locomotive superintendent, a difficulty of a peculiar kind presented itself. It was found that the softened water, which formed no scale in the boilers, had quite the opposite effect in the injectors, feed pipes, and clack boxes. The clacks began to give a great deal of trouble by sticking, and an examination showed that the whole interior of the feed apparatus was coated on the inside with a thick, soft, deposit, which was gradually choking everything up. We were not wholly unprepared for this result, having heard of a similar trouble some time before at a works where a hard magnesia water was being softened by another process. At this works, the boiler injectors had to be cleaned every few days, and the feed pipes at intervals of a few weeks. It was thought this deposit might be due to some imperfection in the softening process, or to imperfect clarification of the water; and we did not altogether anticipate the same result with the water softened and clarified by our process at Derby. It was, however, now evident that a drawback to the use of softened water in boilers did exist, and one which might partly account for the limited extent to which railway companies and other large steam users have adopted existing water softening processes. For, although the scale formed in locomotive boilers by hard water is the cause of very great expense to the companies, less tolerable results might follow from the use of water likely to interfere with and render uncertain the proper working of the feed apparatus upon which the safety of the boilers so greatly depends. The deposit removed from one of the feed pipes gave the following results on analysis, after drying at the ordinary temperature over sulphuric acid:—

Silica	11.05
Alumina	3.68
Ferrous oxide } Ferric oxide. { Calculated to Fe_2O_3	2.23
Calcium carbonate	42.58
Magnesium carbonate	3.33
Magnesium hydroxide	24.87
Organic matter. }	
Water	10.79
Copper (from the feed pipe)	1.47
	100.00

The large extent to which magnesia enters into the composition of this deposit, and the fact that CaCO_3 and Mg(OH)_2 occur in it in proportions which are not far from equivalent, whilst in the water the ratio of magnesia to lime is very much less, afford good evidence that the formation of this deposit is attributable in some way to the magnesia contained in the water. The particular portion of deposit which was analysed was entirely formed in a fortnight, during which every tank of water was softened with the greatest care to avoid excess of lime. A clack which was put into one of the clack boxes clean, and was taken out at the end of this fortnight, is upon the table, and another which had been in use for a month is also shown. The deposit formed in the feed pipes during this period was much thicker than it is upon the clacks.

In order to determine whether the formation of this deposit was a property of the clear softened water free from any trace of suspended matter, some of the water was filtered, and the clear, bright water was heated for some time to nearly 200 F. in a closed glass flask. Nothing appeared to separate at first, but on shaking the water round in the flask, an exceedingly thin film peeled off the interior and broke up into little coils which floated about in the water. These films contained both CaO and MgO . The cause of the deposit was now apparent; the water, softened in the cold, gave a slight further precipitate on heating, and this, though only trifling in amount, was quite enough

to account for the observed effects. The four boilers using softened water are all supplied by one exhaust injector, and through this injector and the feed pipes about 20,000 gallons of water pass in one day. If each gallon of water were to deposit in the hot injector and pipes only one-third of a grain of solid matter, the total deposited in one day would amount to nearly 1 lb. The proportion which actually adheres to the pipes must be less than this. The experiment was afterwards made of passing a little CO_2 into another quantity of the water before heating it in the flask, and this was found to prevent further precipitation. The remedy therefore lay in carbonating the softened water. Having obtained permission to make the experiment, between the softening tanks and the small donkey pump, which at present lifts the softened water into a small storage tank, we interposed a siphon pipe, the upper bend of which is elevated a few feet above high-water level in the softening tank. Entering the bend at the top of the siphon pipe a small branch pipe was fixed, communicating with a scrubber, and from the scrubber a pipe was carried into the chimney-stack. The chimney gases were thus aspirated through the scrubber into the descending column of water, and after passing through the pump the residual gases escape into the air from the end of the discharge pipe above the storage tank. The injector and feed pipes having been cleaned (an unnecessary proceeding, for we find the carbonated water soon cleans them) the carbonated water was used for a few weeks, and then the clack boxes were opened and examined, with the result that not a trace of deposit was found. But a longer trial was required, and as the smoke in the chimney gases gave trouble, the pipe was removed from the chimney and was made to draw the products of combustion from a Bunsen gas flame instead. A lengthened trial has proved that the process is completely successful and involves very little extra expense or trouble. A clack is exhibited which was taken out after four months' immersion in the hot carbonated water, and which is as free from deposit as the day it was put in. To use coal-gas, except for purposes of experiment, would of course be too expensive, and in the plant now being completed at Derby smokeless gases from a coke stove will be used. These will be pumped into the main which conveys the softened water into the storage tank, in definite proportion, so as to impregnate the softened water with just enough CO_2 to produce an excess. If the quantity used amount to 3 grains per gallon, the volume of gas required for 10,000 gallons will be yielded by the complete combustion of only 1.3 lb. of coke containing 90 per cent. of carbon, and the cost will of course be quite insignificant. The gases will not be scrubbed, as there is no need to do so. For if the coke used contain 2 per cent. of sulphur, if all this sulphur were to be oxidised to H_2SO_4 , the quantity of H_2SO_4 per gallon of water would amount to only 0.055 grain, and as the softened water of 3 degrees hardness contains fully fifty times as much alkali as is required to neutralise this amount of acid, the sulphur in the coke cannot possibly do any harm whatever. No difference is perceptible in the condition of the boilers since the carbonating of the softened water was commenced. Not only is the softened water after carbonating in this simple and inexpensive manner more suitable in every way for feeding boilers, but it is better adapted than uncarbonated softened water for many other purposes, such as tanning and dyeing; it will also be more palatable; and it will form no deposit in town mains. It will, on the contrary, have a tendency to remove the deposit which has formed in old mains, though of course care would have to be taken that the solvent action of the carbonated water does not extend to the iron of the mains themselves. It would be easy to avoid this, as the proportion of CO_2 which is put into the softened water admits of easy adjustment.

A number of experiments have been made with the object of investigating the behaviour of dilute solutions of magnesium carbonate towards lime. A strong solution of magnesium bicarbonate was prepared by suspending washed magnesia in distilled water, passing CO_2 for some time, and filtering. 10 cc. of the clear solution contained:—

	Grm.
MgO (by alkalimetry)	0.0489 (= 2 CO_2 , 0.1070 grm.)
MgO (by precipitation)	0.0509
CO_2 (by absorption and weighing) 0.1064	

According to the alkalimetric result, the solution contained 700 grains per gallon of $MgCO_3$. 30 volumes diluted with distilled water to 1,000 volumes made a solution containing 21.5 grains per gallon of $MgCO_3$, and this was used for the experiments. The amount of CO_2 contained in the distilled water used for diluting being known, it was easy to calculate the exact volume of lime-water needed for the reaction—

Three series of experiments were made, and in each series, besides a quantity with the equivalent proportion of lime, six quantities were mixed with decreasing volumes of lime water, and six with increasing volumes. The solutions were mixed in small flasks, closed by rubber stoppers, agitated at intervals during the first half-hour, and then allowed to stand overnight at the temperature of the laboratory, those in Series 3 being left for exactly 24 hours at a temperature of 52–62° F. 70 cc. of each clear solution (in Series 1 and 2 after filtration; in Series 3 without filtration) were titrated by a standard acid of such a strength that 1 cc. = 0.001 gram $CaCO_3$. The results obtained are given in the following table:—

MAGNESIUM BICARBONATE SOLUTION PRECIPITATED BY LIME-WATER.

Approximate Deficiency or Excess of CaO used.	Alkalinity of the Softened Water calculated as $CaCO_3$.		
	Series 1.	Series 2.	Series 3.
Grains per Gall.	Grains per Gall.	Grains per Gall.	Grains per Gall.
0	0.2	8.2	5.9
2.5	5.7	6.45	5.1
5.0	5.1	5.75	4.75
7.5	4.3	5.35	3.9
10.0	3.6	4.65	3.4
12.5	3.7	4.55	3.4
15.0	3.0	4.45	3.9
17.5	1.65	4.7	5.3
20.0	6.9	5.35	9.8
22.5	5.55	6.75	9.55
25.0	5.8	9.7	9.0
27.5	8.0	10.45	11.2
30.0	6.4	8.05	11.0

These figures exhibit considerable discrepancies, which are not attributable to errors of observation, and they show that when the lime is used in excess the results are more uncertain than when it is used in insufficient proportion to saturate all the CO_2 .

Some of the clear filtrate from each experiment in Series 1 was placed in a closed tube, and heated in a water-bath at 170° F. A slight further precipitation took place in each test tube, and it was therefore concluded that the deposit which takes place in the feed pipes of steam boilers using softened water cannot be prevented by altering the proportion of lime used in softening.

In order to investigate more exactly the precipitation of magnesia by lime, it was decided to repeat three of these experiments with larger quantities. Accordingly, three separate litres of the diluted $MgCO_3$ solution were placed in flasks, and were mixed with the following volumes of lime-water of known strength, viz. 321 cc., 354 cc., and 387 cc.; these volumes representing respectively a deficiency of CaO amounting to 2.4 grains per gallon, the theoretical proportion of CaO , and an excess of CaO amounting to 2 grains per gallon. The flasks were closed with rubber stoppers and shaken at intervals for a short time, then left till next morning. The precipitates having settled, it was

then observed that the 321 cc. and the 354 cc. quantities were bright, whereas the 387 cc. quantity was opalescent in appearance.

After the 354 cc. quantity, i.e., the quantity containing the theoretical equivalent of CaO , had stood altogether for 22 hours, about half the clear water was transferred to a silver bottle, tightly closed with a rubber stopper, and heated for two hours in a water-bath at 170° F. 500 cc. of the remainder of the clear water were used for estimation of CaO and MgO . At the end of the two hours the silver bottle was placed in cold water, and, when cold, the contents were filtered, and 500 cc. of the filtrate were used for estimation of CaO and MgO . The 321 cc. quantity was treated in precisely the same manner, except that it was allowed to stand for 30 hours before being proceeded with. The 387 cc. quantity, i.e., the quantity containing an excess of lime was, as already stated, opalescent. When an attempt was made to filter it, it was observed that the solution at first passed through opalescent, but after a short time it began to come through bright, and at the same time the filtration became extremely slow, and it could be plainly seen that this was caused by a separation of what looked like magnesia from the water before it passed through the paper. The experiment was subsequently started afresh and the same opalescent fluid was again obtained. On this occasion the flask was allowed to stand for 116 hours, and still the opalescence persisted. The contents were therefore treated as follows: About half the opalescent liquid (which was quite free from visible particles) was carefully siphoned off and was heated in a closed silver bottle for three hours at 170° F. with occasional agitation. The bottle and its contents were then cooled, and the contents were poured into a flask and corked up. The liquid still retained its opalescent appearance, but a very small precipitate was now visible in it, and this was allowed to settle, which took a long time. Altogether, this solution, which had been heated and cooled, stood for four days in the closed flask and still the opalescence persisted, and only the traces of precipitate separated by heat had settled to the bottom. 500 cc. of the opalescent fluid were siphoned off without disturbing the precipitate, and the CaO and MgO were determined. 500 cc. of the original opalescent liquid, which had not been heated, were also treated to separate the CaO and MgO . Unfortunately the MgO estimation in this quantity was lost. The results of the three experiments were as follow:

MAGNESIUM BICARBONATE SOLUTION PRECIPITATED BY LIME-WATER.

Volume of $MgCO_3$ Solution.	1,000 cc.	1,000 cc.	1,000 cc.
	321 cc.	354 cc.	405 cc.*
Volume of Lime Water.			
The Mixed Solutions contain	2.4 grs. per gall. of CaO less than the quantity equivalent to the CO_2 .	The theoretical equivalents of CO_2 and CaO .	2 grs. per gall. of CaO more than the quantity equivalent to the CO_2 .
Analysis after precipitation in the cold.			
	Grains.	Grains.	Grains.

	Grains.	Grains.	Grains.
CaO	0.55	0.94	2.16
MgO	1.13	0.44	7.23
Hardness	3.79	2.74	21.84

* A different solution of lime was used.

The result of this third experiment is remarkable. The MgO originally present, calculated on the total volume of solution (1,405 cc.) amounted to 7.31 grains per gallon, and of this 7.23 grains, i.e., practically the whole of it, failed to precipitate, being held up, not as carbonate but as hydroxide, and forming with the CO_2 free water the peculiar opalescent liquid. We appear to have in these experiments a complete

explanation of the discrepant statements which have appeared as to the possibility of softening magnesia-hard waters by Clark's process. So long as the lime-water is used with care, avoiding the least excess, keeping the quantity rather less than that necessary to combine with all the CO_2 , the $\text{Mg}(\text{OH})_2$ falls at first as a flocculent precipitate with the CaCO_3 , and then they crystallise together, forming a coarsely crystalline precipitate which settles well, and a bright softened water which filters easily. But if the lime be used in excess, sometimes when the exact equivalent quantity is used, there is a tendency for a part or a whole of the $\text{Mg}(\text{OH})_2$ to remain in a peculiar colloidal condition, whilst the CaCO_3 assumes the form of a very fine crystalline precipitate which sometimes settles very slowly. When an attempt is made to filter the water in this condition, it at first passes through the filters, but soon the magnesia begins to separate upon the filters in a form which rapidly clogs them and makes them useless. We do not doubt that the softening of magnesia-hard waters by means of lime, or sodium carbonate and lime, can be satisfactorily and economically carried out in the form of plant designed by us, and the hardness brought down to 4 or 5 degrees.

It seemed desirable to ascertain to what extent the solubility of magnesia or magnesium carbonate in water is influenced by the presence of such sodium salts as occur in softened water. Five equal volumes of the dilute MgCO_3 solution were therefore placed in separate flasks, and each was precipitated by the addition of the same calculated volume of lime-water. In one experiment the MgCO_3 solution was used pure; in a second, sodium sulphate was dissolved in the MgCO_3 solution in such quantity that after the lime-water was added there would be 100 grains per gallon of Na_2SO_4 ; in the third experiment NaCl , and in the fourth NaNO_3 , were used in the same proportion; whilst in the fifth experiment all three sodium salts were added. After allowing the mixed solutions to stand for 24 hours, 70 cc. of each clear softened water was titrated. The results obtained were as follows:—

Sodium Salts in the Softened Water.	Alkalinity of the Softened Water (Calculated to CaCO_3).
	Grains per Gallon.
1. None.....	1.0
2. Na_2SO_4 , 100 grains per gallon.	4.85
3. NaCl , 100 grains per gallon ...	1.0
4. NaNO_3 , 100 grains per gallon..	1.0
5. Na_2SO_4 , 100	5.2
NaCl , 100	
NaNO_3 , 10	
} grains per gallon	

From these results it appears that the influence of sodium salts is inappreciable, except in the case of the sulphate, and even in this case the solubility is only increased to the extent of about 1 degree of alkalinity.

Finally, to test the conclusions arrived at, an artificial magnesia hard water was prepared, containing in 1 litre:—

34.0 cc. of the strong MgCO_3 solution,
0.301 grm. of gypsum,
1.62 grm. of $\text{Na}_2\text{SO}_4 \cdot 10 \text{H}_2\text{O}$,
0.714 grm. of NaCl ,
0.113 grm. of NaNO_3

The analysis of this water stated in the usual manner would be about as follows:—

	Grains per Gallon.
CaCO_3	25.5
CaSO_4	15.3
MgSO_4	30.7
Na_2SO_4	50.0
NaCl	50.0
NaNO_3	10.0
	181.5

The water was first of all analysed by determining the alkalinity, the CaO , and the MgO . Some of the water was then boiled very rapidly for one hour in a silver beaker, the volume being maintained by additions of distilled water kept boiling in a silver bottle. After filtering, cooling, and making the boiled water up to the original volume, the alkalinity, the CaO , and the MgO were again determined. Some of the water was then softened by adding to it.

(1.) As much Na_2CO_3 dissolved in a little water, as was equivalent to the total $\text{CaO} + \text{MgO}$, deducting as much as was equivalent to the total alkalinity of the original water.

(2.) As much lime water as was necessary to give a pale straw colouration with silver nitrate, increased by as much as was equivalent to the total MgO .

Altogether, 500 cc. of the hard water were taken, and there was added 0.29 grm. of pure Na_2CO_3 dissolved in a little water, and then 192 cc. of lime-water (1 cc. = 0.001167 grm. CaO). The precipitate was at first very voluminous, but it quickly became coarsely crystalline and settled nicely. The clear softened water after standing over night was analysed for alkalinity, CaO , and MgO . All the results obtained are arranged in the following table:—

EXPERIMENTS WITH MAGNESIA-HARD ARTIFICIAL WATER.

	Original Water.	After Boiling.	After Softening.
CaO	20.86	8.49	1.57
MgO	11.08	9.87	0.49
Alkalinity (grains per gallon CaCO_3).	26.65	1.70	5.70
Calculated hardness (= grains per gallon CaCO_3).	1.01

DISCUSSION.

Mr. C. G. CRESSWELL was much interested by the fact that although the authors had added their chemicals both separately and in combination, very little difference was shown in the results produced. It was to be noted, however, that the authors were not dealing with a sewage, but with water, and therefore the results should not differ materially. He would be glad to know whether the organic constituents of the water had been determined after treatment by the reagents together and separately, and if so, whether they differed as much as might be expected. People were in the habit of ridiculing Maignen's statements that water was purified and softened by the simultaneous use of soda, lime, and alumina; but the results brought forward by Messrs. Archbutt and Deeley showed that as regarded softening, the effects were not very different from those claimed by Maignen, and that the object of employing alumina was not to make a lake of organic bodies, but to bring down the inorganic constituents.

Mr. A. H. ALLEN wished to know what the authors understood by the term "calculated hardness." He hoped that they meant the amount of lime and magnesia calculated into their chemical equivalents of carbonate of calcium, and not according to any fancied hardening power possessed by magnesia as distinguished from lime. The term seemed to him to be obscure; because "hardness" varied in an erratic manner, and one could not predict what the hardness of a sample of water would be merely from the amount of lime and magnesia it contained. Secondly, he was not sure whether he had rightly understood Mr. Archbutt as to the method employed in preparing bicarbonate of magnesium by passing carbon dioxide through water containing magnesia in suspension.

Mr. ARCHBUTT: The current of gas was continued until a good deal of the magnesia was dissolved, but not quite all.

Mr. ALLEN, continuing, said that under those circumstances the authors would no doubt expect to obtain no excess of carbonic acid, and he would like to know whether that warrantable expectation had been fulfilled. He had made some experiments on the similar question of the solubility of carbonate of calcium in carbonic acid water with a view to ascertain if there was any foundation for the statement that a bicarbonate of calcium exists. For his part, he doubted the existence of any such thing. That calcium carbonate dissolved in carbonic acid water was correct; but that the additional amount of carbonic acid required for its solution was equal to the carbonic acid combined with the lime was, he thought, very questionable. At any rate, his own experiments had failed to convince him of any such relationship. If any excess of carbonic acid was in the authors' magnesia solution, notwithstanding their caution in leaving some magnesia undissolved, it might throw their subsequent calculations wrong. He hoped that the authors had foreseen that danger and provided against it. The paper had thrown new light on a somewhat obscure subject, and it was very satisfactory to find that the authors had attained so much success by a proper and scientific use of their reagents.

Mr. W. THORP was surprised to hear the authors state that the lime method of purification was not adapted for the treatment of river waters. The authors had quoted Homersham to that effect; but he fancied that they must have quoted him without the accompanying qualifications; for, although there could be no doubt that clear spring waters were most suitable, still he was under the impression that river waters had been successfully treated by that method. He had had no experience of the particular water referred to, but looking at the figures before them he hardly thought it deserved the title of "a filthy water." The hardness did not seem to be considerable, and there were no figures indicating a large amount of pollution for a river water. He had not quite caught the names of all the chemicals employed, and would like to know if there were any chlorides among them, for the quantity of sodium chloride in the samples was greater after treatment than before, and unless this was due to treatment by a chloride, he did not see where it could come from. The mechanical arrangements were very ingenious, and there were only two questions which he wished to put respecting them. First, was the "well" really necessary? He thought that the water would find its way to the inlet of the trajectory without the use of the guiding walls of the well itself. In fact, it seemed to him that the walls of the well rather represented the first ideas of the design, and might be discarded. Secondly, had the authors considered and ascertained the expense of the blower? Probably they had, but many people thought that the blowing of air through water was a very simple matter, forgetting that the work to be done was precisely that of pumping an equal quantity of water to a height corresponding to the depth to which the air had to be blown in. If the air had to be blown in, say, 10 ft., the work was equivalent to lifting an equal volume of water 10 ft. It was obvious that that might run away with a great deal of power.

Mr. R. H. HARLAND agreed with the previous speakers in congratulating the authors, and wished to observe that the difficulties they had spoken of were always found in softening waters containing magnesium salts. After the addition of lime water in even less than the proper proportion, a further precipitation occurred, but not until from 12 to 24 hours after the water had passed through the filter. Then a distinct crystalline sediment was found at the bottom of the vessel, consisting of a magnesium salt, and the water was softer by one or two degrees. It seemed to him that the whole question must be looked at from a different point of view. It was all very well to have tanks holding 20,000 gallons, and all the other arrangements described by the authors. But generally speaking, steam users put their boilers in confined spaces, where there was no room either for tanks or softening apparatus. Unless users of steam therefore departed from their present plans, the solution of this question would have to be arrived at (if it ever was arrived at) in a totally different way. The

water would have to be treated inside the boilers, with arrangements devised by the engineer in conjunction with the chemist. An apparatus on those lines called the Carroll boiler water purifier had recently been tried in London, and he would like to know whether Mr. Arehbutt had had any experience of it. The inlet of the feed water was so arranged that it passed along the steam space of the boiler from front to back. Part of the inlet pipe was cut away so as to form a channel. The water in its passage became heated to the temperature of the steam. If the working pressure was between 50 and 60 lb. to the square inch, the heat was sufficient to deposit the whole of the calcium sulphate and carbonate, and magnesium carbonate in the front portion of the tube to be removed by blowing off, and the water then flowed into the boiler minus those salts. The apparatus answered well, and the only drawback was the possibility with very hard water, that when pumping, a little of the sediment might be carried forward and deposited in the tubes, but this would not be sufficient to cause a hard scale, and could be swept out. If this trifling defect could be remedied, the apparatus would, he thought, be almost perfect for softening water for boiler purposes.

Mr. B. E. R. NEWLANDS had heard many papers on the present subject, but none so logically worked out as this one. Mr. Thorp was quite right in saying that Clark's process, or modifications of it, had been extensively applied to the purification of river water. Along the Thames many manufacturers had their effluent purified by one or other of the forms of apparatus used in connexion with that process. The difficulty was that the water varied from hour to hour, and so necessitated constant appeals to the laboratory to ascertain the right quantity of reagents to be used. Quite recently, two samples of water before and after purification were sent to him from the neighbourhood of Hammersmith, and his opinion was asked on the merits of the purification effected. The first step he took was to determine the chlorine in each sample, and the result was that he found considerably more in the sample "after purification" than in the other. These samples were taken in good faith, and were honestly intended to represent the effect of the process; but as a matter of fact they represented two different states of the tide, or different conditions of the water. With regard to the precipitation of magnesia, he had found in the early experiments in connexion with the Porter-Clark process that it was impossible to purify water containing much magnesia to the full extent by the addition of the calculated quantity of lime, because the precipitate took a long time to come down, and the water was quite unfilterable. But by reducing the hardness to about 8 degrees only instead of a possible 4, a crystalline precipitate was produced containing a considerable quantity of magnesia, results which the present authors had confirmed by their experiments. He supposed that the authors would not recommend the use of aluminium sulphate except for waters containing flocculent impurities. Its use in other cases appeared to him to be a waste of chemicals, as it required a large quantity of soda or lime and produced a precipitate which added to the bulk to be dealt with. He would like to know the time required to deposit the precipitate in the apparatus under notice as compared with the Stanhope filter. From his own experience he would expect that the rate of precipitation in such a tank as that before them would be about two feet an hour.

Mr. AREHBUDD: It was 98 per cent. in 30 minutes in one case.

Mr. NEWLANDS, continuing, said that showed that the stirring up of the materials had a very advantageous effect. His own experience was that with tanks of 24 ft. cube, using lime alone, about 12 hours was required for settling out, and a somewhat shorter time if soda was used in addition. If the authors had got the same results in 30 minutes, that was a great advance, and seemed to him to completely answer Mr. Harland's criticism as to the amount of room required. He did not at all agree with the idea of purifying water inside the boiler. Many such plans had been tried, but they always failed. It was from all points of view better to clean the water before it entered the boiler.

He had seen Mr. Archbutt's apparatus at work during the Society's recent visit to Nottingham, and was very pleased with it. The inventors could hardly claim that it introduced any startling novelty; but they had brought together a number of appliances which, combined with chemical skill, bid fair to make the process take the place of many of those at present in use.

Mr. W. LAWRENCE inquired as to what temperature the water was raised to by the treatment. It was obvious, he thought, that the precipitation was caused either by the agitation or the steam, and he would like to know which.

Mr. ARCHBUTT: The water is raised 3° F. in temperature by the process.

Mr. L. ARCHBUTT, in reply, said: Mr. Cresswell has asked about the organic composition of the water when the chemicals are added together and separately. I have not gone into that question. An organic analysis was made because it was thought that it might interest some of the members. But I have no reason to suppose that the composition would be very different whichever way the chemicals were used. I do not know why chemists should suppose that the chemicals mixed together soften the water less than when they are added separately. The only difference is that you produce so much caustic soda instead of so much lime and sodium carbonate; but the final results are just the same. Maignen says that the reagents do not interfere with one another; but I think that if he made an analysis he would alter his opinion. I think that why we get better results with mixed chemicals, when we do not stir the mud, is because we then put into the water large particles of calcium carbonate, which has somewhat the same result as stirring up the mud from the bottom. I am glad Mr. Allen asked about the "calculated hardness." The results were got by calculating the CaCO_3 equivalent to the total CaO and the total MgO and adding the figures together; that plan does away with the uncertainty of that wretched soap test which I have long since abandoned, and think it is quite time every other chemist did the same. The strong magnesium bicarbonate solution, as I should have explained, was analysed for magnesia and carbonic acid, the CO_2 being determined by absorption, and it came out almost the exact equivalent for the formation of the bicarbonate. If we add only enough lime to the solution to combine with the CO_2 , existing as bicarbonate, a large quantity of magnesia does not come down. I am going into that question more fully later, but I think that magnesium carbonate is more soluble in water free from carbonic acid than is generally supposed. I was glad to find from Mr. Thorp's remarks that he approves of the process to a limited extent. I think we are justified in describing the water as we have done, not as containing much scale-forming matter, but owing to the large proportion of free and albuminoid ammonia and the high oxygen absorption, and I know that the water receives the sewage of Derby a few hundred yards above where we pump it out. With regard to the sodium chloride, the increase is not very great, and is probably accounted for by the fact that we used soda from the ammonia-soda process, which, I suppose, contains a little undecomposed chloride. As to the well, it is quite true that this was an experimental plant, made before we knew what results we were going to get, and possibly that well may be to some extent modified, but it could not be dispensed with altogether, as there would then be nothing to guide the chemicals into the stream of water produced by the trajectory. With regard to the expense of the blower, I would point out that the steam used by the trajectory as well as the blower raises the temperature of the water only 3° F. It takes a long time for it to cool down those three degrees, so that the water goes into the boiler warmer than before, and therefore we must not charge the whole of the cost to the softening process. But if we did, it would only amount to one-fifth of a penny per 1,000 gallons; and we certainly do not expect to utilise energy without paying for it. I have had no experience of the apparatus mentioned by Mr. Harland; but I would point out that in the case of locomotive boilers the space is limited for putting in such a tube. And further, you

would be practically introducing a condenser into the steam space, and although the fuel consumption may not be increased, ebullition would be more violent, and the steam produced be more loaded with water particles. There are many other openings for softened water besides steam boilers. People who use large quantities of soap find it very expensive to do so with hard water. I am much obliged to Mr. Newlands for his remarks, and am interested to hear that his experience with the Porter-Clark process confirms what I have found in my experiments. I have seen it stated that the best results were got by using excess of lime, which I could not understand. It is true that the chemicals used in our process are the same as those employed by Maignen, or rather that those used by Maignen are the same as have been proposed years before; for some of the earlier patents mention almost every possible chemical, a great number being included in a single patent, thus: "barytes or its soluble salts," "strontia or its soluble salts," and so on. For my own part, I think that the credit of showing that magnesia waters can be softened without the use of caustic soda, if due to any one in particular, is really due to Mr. Wanklyn. With regard to the Stanhope apparatus, no doubt it is very ingenious, but if we can do the same work with a cheaper plant taking up no more space, it is for users to decide which apparatus they will pay for.

SUPPLEMENTARY NOTES ON THE CHEMISTRY OF WHISKY.

By ALFRED H. ALLEN.

IN my recent paper on "The Chemistry of Whisky and Allied Products," I pointed out that the estimation of the ethers from the results of their saponification was liable to be affected by the presence of bodies like aldehyde and furfural, which neutralised more or less alkali and underwent a species of saponification. The amount of alkali which reacts with aldehyde does not appear to have been determined, if indeed it is at all constant. Furfural, on the other hand, has been proved in my laboratory by Dr. A. Colefax to react with caustic alkali in spirituous solution in a proportion corresponding with the formula—

As furfural is always present in pot-still spirit, its presence is liable to materially affect, in some cases, the determination of the ethers by the saponification process.

It has, however, been recently pointed out by E. Mohler (Compt. Rend. 112, 53) that treatment with a solution of aniline in syrupy phosphoric acid renders the aldehyde, furfural, and bodies of similar constitution non-volatile, without affecting the true ethers (ethereal salts). A careful examination of Mohler's process enables me to confirm his statement, provided the spirit be boiled with the phosphoric aniline solution for at least two hours under a reflux condenser. 100 cc. of the spirit is boiled with 1 cc. of aniline and 1 cc. of phosphoric acid of 45° B. (= 1.442 sp. gr.). If then distilled, the ethers pass over unchanged with the alcohol, while the aldehydic bodies remain in the retort. Where furfural is the only aldehydic body present, its amount can actually be estimated from the difference in the volume of standard alkali required for saponification before and after treatment of the spirit with the phosphoric aniline reagent. According to the formula already given, each cubic centimetre of difference in the volume of decinormal alkali required for saponification before and after the aniline treatment represents 0.0192 gm. of furfural.

In my last paper I expressed doubts as to the suitability of an acid solution of potassium permanganate for the oxidation of alcohols to the corresponding acids, especially for the estimation of amyl alcohol by oxidation to valeric acid. The doubts I then expressed have since been fully confirmed, as I have proved the reagent in question to be

very unsuitable for its intended purpose. Commercial potassium permanganate is liable to, and does, contain notable traces of potassium perchlorate, and no care in recrystallising the salt will remove this isomorphous impurity. Commercial permanganate formerly contained much more perchlorate than it does at present, but that the impurity is still to be found is evident from the following experiments. A specimen of well-crystallised potassium permanganate was dissolved in water, pure dilute sulphuric acid added, and then sufficient oxalic acid to decolourise the liquid. Addition of silver nitrate produced a *barely perceptible* turbidity, proving the absence of appreciable quantities of chlorides. Some of the same permanganate was then distilled with water and some of the same sulphuric acid previously used, the latter being added in quantity insufficient to complete the reaction—

With considerable difficulty, and by taking special precautions to avoid spitting, a colourless distillate was obtained. This had a marked odour, resembling that of one of the oxides of chlorine, rather than chlorine itself. It contained no sulphates, but immediately decolourised phenolphthalein, rendering titration with this indicator impossible. These effects were obtained more strongly on adding a small quantity of pure potassium perchlorate to the contents of the retort, so that there can be no doubt the characters of the distillate were due to the presence of traces of perchloric acid or the products of its decomposition. Its presence could scarcely fail to be detected if the distillate from the oxidation process were titrated with baryta water and phenolphthalein, in the manner devised and described by me; but if the distillate were at once boiled with barium carbonate, and the amount of valeric or other volatile organic acid deduced from the weight of the barium salt obtained, the results would be very fallacious. Curiously enough, perchloric acid has a combining weight of 100.5, which is very close to that of valeric acid, 102.

When chloroform is treated with acid permanganate and the product of the reaction distilled, the distillate contains notable traces of chlorine compounds. I do not say that it may not be possible to obtain or prepare chloroform which will not yield these products, but a chloroform so pure that it gave no sensible quantity of volatile acid when treated under pressure with chromic acid mixture, developed a notable quantity of volatile chlorine products when similarly treated with an acid solution of permanganate.

In the course of the numerous experiments recently conducted in my laboratory on the determination of amyl alcohol in spirits, we were struck with the tendency of the

corks employed to absorb valeric acid. India-rubber stoppers not being suitable for use with chloroform, we have adopted the plan of covering all connecting corks with thin tinfoil, to prevent direct contact with the vapours. This device has answered well.

Another curious instance of selective absorption by cork, first observed in my laboratory by Mr. William Chattaway, was in the case of a two-gallon stone bottle of new whisky, which was kept on its side. The cork which closed the bottle was found to have acquired a strong smell of amyl alcohol, and on distilling the portion of the cork which had been in contact with the spirit with water, a distillate was obtained from which amyl alcohol was recovered equal to that in 150 cc. of the whisky, although the cork did not occupy a greater volume than 5 cc.

This experience appeared to point to a remarkable selective absorptive action exerted by cork, and to test the matter further, we added 0.75 per cent. of fusel oil from grain spirit to a pure proof spirit, and kept the fuselated spirit so prepared in contact with cork parings in one case and clean oak shavings in another. After standing for six or seven weeks in contact with the shavings, the spirit was poured off, the shavings dried by pressure between folds of filter paper, packed in a suitable tube, and a current of open steam passed over them. The aqueous liquid thus obtained smelt strongly of fusel oil, and on analysis an amount of amyl alcohol was found equal to 6 per cent. of the weight of the oak shavings and 11 per cent. of the weight of the spirit absorbed by them, as against $\frac{3}{4}$ per cent. in the spirit employed. The cork shavings gave a similar but somewhat less striking result.

It is apparent from these results that vegetable tissue, such as oak and cork shavings, has a curious affinity for the constituents of fusel oil, and they go far to explain the well-known change for the better in the flavour of whisky which occurs by storing the spirit in oaken casks. Animal charcoal is well known to have a similar effect.

Fortunately the means existed for verifying the foregoing conclusions in a very satisfactory manner, by the analysis of some samples of "grog," which is the technical name for the spirit recovered by steaming old whisky casks. A sample of this grog, which had been obtained by steaming a cask which had contained one of the finest brands of pot-still whisky for 18 years, was analysed in my laboratory, as well as the first and last fractions obtained by distilling a similar product. The results are shown in the following table, and for comparison the figures obtained by the analysis of samples of ordinary commercial Irish and Scotch pot-still whisky are also given.

RESULTS OF ANALYSES OF SAMPLES OF WHISKY AND "GROG" (THE SPIRITOUS LIQUID OBTAINED BY STEAMING OLD WHISKY CASKS).

	"Grog" from a Cask in which the finest Pot-still Whisky had been kept 18 Years.		First Fraction obtained on distilling a Sample of "Grog."		Last Fraction obtained on distilling a Sample of "Grog."		Commercial Scotch Whisky.		Commercial Irish Whisky.

From these results it appears that the "grog" was far richer in amylie alcohol than ordinary whisky. It has been suggested, however, that this result is largely, if not entirely, due to the concentration of the amylie alcohol in the pores of the cask through the evaporation of the more volatile constituents. This argument might have some weight in the absence of the shavings experiments; but in the light of these, where no evaporation was possible, there appears to be no other explanation than that the wood exercises a special selective absorption for the higher alcohols of spirit.

The first fraction obtained on distilling grog is of much interest on account of the large proportion of acetic ether contained in it. The smell of the specimen at once indicates the presence of a notable quantity of this constituent, although the odour is somewhat modified by the presence of aldehyde. I may say that the ethers were determined after treatment of the spirit with Mohler's aniline phosphate reagent, so that the influence of aldehyde was eliminated. The presence of so large a proportion as 1·2 per cent. of acetic ether in the first fraction of the grog shows that the action of the wood is not merely physical, as in the absorption of amylie alcohol, but that a chemical change occurs, resulting in the formation of aldehyde and further oxidation of this to acetic acid, which apparently is very rapidly and completely etherified, for the proportion of free acid is extremely small.

The last fraction obtained by the distillation of the grog is equally interesting. It contains a very large amount of amylie alcohol, evident even to the smell, and is also rich in furfural. From the difference in the volumes of alkali required before and after treatment with the aniline phosphate reagent, I estimate the proportion of furfural at 0·076 grms. per 100 cc. or 47·7 grains per proof gallon. For the above sample of grog and fractions obtained by its distillation I am indebted to the kindness of a distiller. I have to acknowledge the zealous collaboration of Mr. William Chattaway in the researches of which these notes give an outline.

DISCUSSION.

Mr. G. T. HOLLOWAY inquired whether the author had used animal charcoal instead of cork or wood shavings, it being being well known that that material was largely used in Germany. Referring to the author's remarks on permanganate, he might mention a curious experience of his own. He had noticed an evolution of gas of distinctly chlorous odour, on removing the stopper from a bottle in which a dilute solution of permanganate, slightly acidulated with sulphuric acid, had been kept for a few days. He had had the permanganate by him for 10 years, and therefore it probably was more impure than that which was now supplied.

Mr. OTTO HEHNER would like further evidence of the oxidation of ethereal bodies in the pores of the wood. It seemed to him that if the fusel oil had concentrated in the wood by absorption the ether might have done the same. Yet he understood Mr. Allen to attribute increase in the one ease to absorption, and in the other ease, the formation of ethers, to oxidation. Comparative figures showing the absorption of higher alcohols by wood and by animal charcoal respectively, would be highly important and interesting.

Mr. ALLEN, in reply, said that probably the ethers were absorbed by the wood as Mr. Hehner had suggested, but there was evidence of their formation also. Aldehyde was formed, and he assumed that it was a product of the oxidation of the alcohol, and that it had subsequently been further oxidised to acetic acid and then become etherified to acetic ether. The proportion of ethers in the spirit was only 40 or 50 grains to start with; the quantity found in the first fraction of the grog was upwards of 500 grains per gallon, and therefore he thought it was an oxidation process. But the matter was not so simple as the figures on the board appeared to make it; for the ethers that came from the cask were not all acetic ether. There was a certain amount which when saponified yielded acids which were not volatile. It was plain therefore that there was still a good deal to learn

about the chemistry of the subject, and the results which he had brought forward would serve to suggest further inquiries in the future.

Mr. W. FOSTER inquired whether there was any evidence as to the amount of aldehyde and furfural in ordinary fresh spirits.

Mr. ALLEN replied that there was no known process for accurately estimating aldehyde, and it would be seen from last week's "Chemical News" that doubt was thrown on the process upon which they had hitherto relied for detecting and roughly estimating it. That doubt was undeserved, and the best test for aldehyde was Gayon's reagent, a solution of rosaniline reduced by a large excess of sodium sulphite. This reagent detected small quantities of aldehyde by forming a crimson coloration. Furfural existed in some cases in sensible quantities, and might be present to the extent of 30 to 40 grains per proof gallon. It was characteristic of pot-still spirit, and did not exist in steam-distilled spirit; but he could not endorse the statement of Dr. James Bell that the proportion was so constant in pot-still spirit that the presence and proportion of patent still-spirit could be inferred from the deficiency.

Chairman: L. Archbutt. Vice-Chairman: Jno. R. Ashwell. Treasurer: J. M. C. Paton. Committee: C. H. Field, E. W. Small, C. Taylor, and Sir John Turney.

Meeting held on Thursday, May 7th, 1891.

MR. L. ARCHBUTT IN THE CHAIR.

AN IMPROVED OIL-BATH FOR DYEING LABORATORIES.

BY R. LLOYD WHITELEY, F.I.C., F.C.S.,

Lecturer and Instructor in Dyeing.

IN fitting up the new dyeing laboratory at University College, Nottingham, I was compelled to devise an oil-bath which eliminated the risk of fire attendant on the use of the old form. I think that I have succeeded in this, although I cannot, unfortunately, do away with the smell produced by the use of oil or glycerin.

In the old form, the pots used for dyeing operations were placed directly in the oil in the bath, and it was easy, by faulty manipulation or by the cracking of the pots when put

cold into hot oil, to introduce water into the oil, and thus have it boiling over out of the bath; and as a large flame is necessary to produce the required heat, there is thus considerable risk of fire.

Fig. 1.

The new bath is made in two parts. Fig. 1 (*a*) represents the lower portion, which is made of copper welded and brazed together (solder must on no account be used). It measures $21\frac{1}{2}$ in. \times $15\frac{1}{2}$ in. \times 6 in., and has an internally-projecting rim *b* on the inside, so that if by any carelessness the temperature should rise to the boiling point of the oil, it will be thrown towards the centre whilst boiling. The upper portion of the bath *c* fits into the lower by means of the rim *d*, which projects downwards about $\frac{3}{4}$ in. It will be seen that the upper portion is tray-shaped. It is slightly larger in area than the bath proper, viz., 17 in. \times 22 in., and is about $\frac{3}{4}$ in. deep. In it are firmly fixed six copper cups, 5 in. deep \times $5\frac{1}{2}$ in. wide, to receive the dye-pots. Fig. 2 represents one of the cups, *a*, in section, with

Fig. 2.

a dye-pot in it, the annular space *b* containing glycerin. The tray is also provided with an aperture for the introduction of a thermometer, and at either end projects a handle, by means of which the flaps *c* can be moved, and the oil thus be stirred, so as to equalise its temperature.

Cotton-seed oil is used in the baths, at a temperature of $160-170^{\circ}\text{C}$., and glycerin is put in the cups which hold the dye-pots. With an arrangement of burners as shown in Fig. 3, I can boil a litre of water in each of the six pots in 35-40 minutes, starting with everything cold.

Fig. 3 represents the arrangement of burners which was adopted after a number of trials with different burners. The stand *a* is of the ordinary type, 5 in. high, provided with a shield of sheet iron $3\frac{1}{2}$ in. deep on three sides. The consequence of such an arrangement is that a rush of flame takes place towards the *back* of the bath and the pots at the back, under the ordinary setting, always boil before the others; this fault is intensified when the whole bath is heated by a central longitudinal burner or by one central round one. I overcame this in part by the introduction of stirrers to keep the oil mixed, but then tried other arrangements of burners.

Fletchers sent me two of their jet burners fitted together so that there was a burner under each row of pots, but I found that in consequence of the gas entering at the centre of the burner the central pots in each row boiled some time before the others.

Fig. 3.

I finally adopted the present arrangement, not only because I obtained the most regular heating, but also from the standpoint of economy in gas. The burners are arranged $6\frac{1}{2}$ in. apart under the bath, but whilst the distance from *b* to the front of the bath is 4 in., the distance from *c* to the back is 7 in., so that the whole of the bath is equally heated. Several different burners were tried either alone or in pairs, and it may interest some members to have their relative value as shown by the amount of gas burnt (for which I have to thank the kindness of Mr. Johnson, of the Corporation Show Rooms) and work done.

	Gas consumed at $16\frac{1}{2}$ " 10 pressure.	
1. Two of Fletchers' Longitudinal jet burners coupled consumed...	60	cu. ft. per hour.
2. Two of Fletchers' round slit burners	27	" "
3. Three of Wright's 310 burners (as adopted)	43 $\frac{1}{2}$	" "
4. Two of Wright's 312 burners.....	54	" "
5. Two of Wright's 322 burners.....	72	" "

Of these, No. 2 performed the work required far too slowly, No. 5 was the quickest, No. 4 the slowest, No. 1 and No. 3 were about equal; but the expenditure in gas was much less with No. 3 than No. 1, and the heating more regular. The work required was to heat the oil in the bath to 170°C ., and 1 litre of water in each pot to 100°C .

Briefly, the advantages of the oil-bath and its setting may be summed up thus: (1.) Regular heating of the dye-pots; (2.) Almost complete immunity from fire risks.

Its disadvantage is the smell from the heated glycerin. This is owing mainly to the fact that the dye-pots are not all one size, and if there is enough glycerin in the cups for one set there may be too much for another, and the glycerin consequently overflows on to the tray, and getting burnt, gives off its disagreeable odour.

A NOTE ON LÖWENTHAL'S METHOD OF TANNIN ANALYSIS.

BY R. L. WHITELEY, F.I.C. AND J. T. WOOD.

A SHORT time since one of us analysed by Löwenthal's method some samples of spent larch bark and obtained much too high results, viz. :—

	Per Cent.
No. 1	7.54
No. 2	6.40
No. 3	8.12

of tannin, stated in terms of oxalic acid on the dry bark. Since no defect in the working or leaching of the bark could be detected which would account for these results, several more samples were taken, dried, and ground, and the results obtained were—

	Per Cent.
No. 4	0.73
No. 5	1.24
No. 6	2.80

As these results were in accordance with expectation, sample 3 was once more analysed and showed 3.71 per cent.

On comparing notes we found that the great discrepancy in our results was apparently due to the different strengths of extracts used by us. In the first three cases about 5 grms. of bark per litre only had been used, whilst in the last three cases from 21 to 28 grms. per litre. These experiments showed that Löwenthal's method was evidently very defective in estimating small quantities of tannin matters.

To further test this we analysed two samples of larch bark under different degrees of dilution and also a sample of sumac.

The percentages of the larch-bark tannin and also of the non-tannin are expressed in terms of oxalic acid, whilst that of sumac tannin is expressed in Neubauer's equivalent.

	Larch No. 1.		Larch No. 2.		Sumac.	
	Tannin.	Non-Tannin.	Tannin.	Non-Tannin.	Tannin.	Non-Tannin.
	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.	Per Cent.
Original solution.....	12.81	12.77	3.83	17.97	9.99	
Original solution diluted to 20 per cent.	17.05
Original solution diluted to 10 per cent.	..	15.43	0.53
Original solution diluted to 5 per cent.	..	*11.97	1.05
Original solution diluted to 50 per cent.	19.68	12.48	
Original solution diluted to 12½ per cent.	26.89	13.98	

	Grms.	Cc.
No. 1 larch contained.....	11.3365	1.000
No. 2 larch contained.....	8.4713	in 450
Sumac contained.....	8.0000	in 1,000

These results thus quite confirm the previous ones; they show that dilution to too great an extent affects the results very deleteriously, making them much too high. It is true that the result marked * would seem to oppose this statement, but it must be borne in mind that in such a weak solution an error in titration of 0.1 cc. would affect the result by 2 per cent., i.e., 11.97 might easily be 13.97. In works on analysis, operators are cautioned against too strong solutions, it having been stated that the total permanganate used should not exceed 1½ times that required for the indigo solution alone, but our experience shows that even where 1½ times that amount is used, the error is very small, whilst dilution much below a strength of from 1.8—2.0 grms. of tannic acid produces a large error.

Meeting held on Tuesday, March 24th, 1891.

MR. L. ARCHBUTT IN THE CHAIR.

SOME RECENT ADVANCES IN PHOTOGRAPHY.

BY C. H. BOTHAMLEY, F.I.C.,

Assist. Lecturer on Chemistry in the Yorkshire College.

ABSTRACT.

THE recent addition to photographic processes that can be regarded as real advances from the practical point of view are limited to three printing processes, two of which belong to the same class and represent an entirely new type of photographic process, whilst the third is a development of an improvement of an older process which previously had no practical value. The discovery of the reversing action of thiocarbamides by Waterhouse is so recent that it is not possible to express any definite opinion as to its actual utility.

The two processes belonging to a new type are both based on the effect of light on diazo-compounds, and hence are fitly termed diazotype; the one is generally distinguished as *Feer-type* and the other as the *Priniline process*.

Feer-type, which derives its name from the inventor, Dr. A. Feer, is based on the fact that diazosulphonic compounds form no colouring matters with phenols and amines, but on exposure to light the sulphonic compound is decomposed with liberation of the diazo-compound, which is then able to exert its power of forming azo-colouring matters with phenols and amines. The diazo-compounds originally recommended (Ger. Pat. 53,455, December 5, 1889) were sodium toluenediazosulphoate and sodium ditolyl-tetrazo-sulphonate. A 2.5 or 3.0 per cent. solution of one of these salts is mixed with an equivalent quantity of an amine or of a phenol (such as resorcinol or β -naphthol) and caustic soda. Paper or fabrics are immersed in the solution and dried. When exposed to light the diazo-compound is liberated in quantity proportional to the quantity of light-action and being intimately mixed with the phenol or amine at once forms an azo-colouring matter. If the paper or fabric is exposed behind a semi-transparent body like an ordinary photographic negative, it is obvious that the greatest quantity of colouring matter will be found where the semi-transparent body allows most light to pass, and hence a positive image is obtained from a negative, and *vice versa*. The time of exposure required is stated to be 10 to 15 minutes in direct sunlight. After exposure the print is washed in water, or if an amine has been used, first in dilute hydrochloric acid, and afterwards in water.

My own experiments are as yet few in number, in consequence of some delay in obtaining the necessary material, and are of interest only as confirming in a general way the statements of the inventor. They were made with sodium diazo-pseudo-cumidine-sulphonate, which has been recommended by Feer in place of the toluene or di-tolyl derivative. When it is dissolved in water with equivalent quantities of β -naphthol and sodium hydroxide and paper is immersed in the solution and dried, it yields surfaces which are very sensitive to light. Exposure for only 10 seconds to March sunlight on a not very bright day gave a deep pink colour, and exposure for one minute gave a deep red, which was only very slightly increased in intensity by doubling the exposure. Some "nature prints" made with fern leaves were very satisfactory and showed a considerable amount of detail and structure.

I observed that the rate of change became very much slower as exposure was continued, doubtless because the colouring matter formed in the surface acts as a protective screen to the unchanged material behind. I also found that a print could readily be obtained by means of magnesium ribbon, and that even exposure for 20 minutes at a distance of 6 in. from an ordinary No. 5 gas burner produced a readily recognisable quantity of colouring matter. So far, however, I have made no experiments with the spectrum.

The priniline process has already been described by its inventors before another Section of the Society (this Journal, 9, 1001—1002), and it is therefore only necessary to say that, as a rule, the results of my own experiments confirm their statements.

Phenol, which is recommended for the production of a yellow colour with the unaltered diazo primuline, behaves in a somewhat peculiar way. When the fabric containing the diazo primuline is immersed in the alkaline solution of phenol, it acquires a deep orange-red colour, but on washing with water this slowly changes to yellow. Prolonged washing is required to complete this change, but if the washing is stopped at an intermediate stage the distribution of the colouring matter on the fabric is usually very irregular.

Quinol (hydroquinone) gives only a pale yellow colouring matter, and is practically useless as a developer.

The inventors recommend solutions of the developers containing about 0.25 per cent. of the active constituent; the British Journal of Photography (37, 658) recommends solutions containing 0.7 to 1.4 per cent. (3 to 6 grains per ounce). I have not been able to recognise any advantage in the use of the stronger solutions.

The same journal (*loc. cit.*) recommends eikonogen (sodium amido- β -naphthol- β -sulphonate) as a developer for a black colour, and pyrogallol as a developer for a brown colour. The inventors in their later paper state that eikonogen as a developer gives a blue colour.

My own experiments, made with various samples of eikonogen, and with solutions of various degrees of concentration, confirm the statement of the inventors that this developer gives a blue colour. It may be useful to emphasise (1) the importance in this case of making the final washing with water slightly acidified with tartaric acid, and (2) the fact that prints produced with this developer must not be soaped.

Pyrogallol must be used in alkaline solution and the surface of the liquid absorbs oxygen from the air with great rapidity and becomes very dark in colour. Unless, therefore, the fabric is kept entirely at the bottom of the vessel and out of contact with the discoloured layer of liquid it is certain to become stained. Moreover, in the character of the colour produced, pyrogallol is decidedly inferior to meta-phenylene-diamine.

According to my experience the developers giving the most satisfactory results are β -naphthol, resorcinol phenol, α -naphthylamine, metaphenylenediamine, and eikonogen.

The great objection to the use of naphthylamine and some other amines is that they cling most tenaciously to the fingers, and have a very disagreeable smell. It may be useful, therefore, to point out that in this and all similar cases the smell can be immediately and entirely removed by immersing the fingers, &c. in a very dilute acidified solution of sodium or potassium nitrite.

When it is desired to apply the primuline process to paper, I recommend that the paper should first be sized with a hot solution containing 2 per cent. of gelatin and a small quantity of chrome alum, and dried. It is then floated on a hot solution of primuline, care being taken that none of the dye gets on the back of the paper, and again dried. When required for use it is diazotised and developed in the same manner as a fabric.

In order to apply the process for the production of transparencies on glass, the following mixture may be used: Gelatin, 5 parts; primuline, 2 parts; water, 100 parts; chrome alum, 0.025 to 0.1 part. The solution is heated to a few degrees above its melting point and poured on carefully cleaned and levelled glass plates, the thickness of the layer depending on the depth of colour required. As soon as it has thoroughly set it is diazotised by immersion for several minutes (according to the thickness of the film) in an acidified solution of sodium nitrite, washed with water, and dried. The quantity of chrome alum that can be added without precipitating the gelatin from the solution varies with the quality of the gelatin; it is desirable to use as much as possible, since the film is subjected to treatment with acids and alkalis in the subsequent stages, and unless it has been properly aluminated it is very liable to leave the glass.

With respect to the permanence of the prints obtained by the primuline process and Peet's process, it may be pointed out that in both cases the image consists of an azo-colouring matter, and most of these, as is well known, fade when exposed to very bright light for any length of time, whilst, on the other hand, they are very stable when exposed only to the diffused light of ordinary rooms.

It does not seem at all likely that either of these processes will displace the ordinary photographic printing processes for general purposes. At the same time the variety of colour that can be obtained, and the ease with which they can be applied to fabrics, makes them of considerable value for decorative purposes, and it is in this direction that their utility will probably be found to lie.

The third process, which the inventor, Dr. W. W. A. Nicol, calls *Kallitype*, is of an entirely different character, and is based upon the old observations of Herschel and of Hunt that ferric salts when exposed to light are reduced to ferrous salts, and the latter precipitate metallic silver from solutions of silver nitrate. Neither in the hands of Herschel nor Hunt did the method acquire any practical value, and Nicol's improvement consists in the careful working out of the details of the process. Paper is coated with ferric oxalate, citrate, or tartrate, or a mixture of these, and after exposure is treated with an ammoniacal solution of silver nitrate mixed with a large proportion of an alkaline salt of an organic acid, the function of the latter being to prevent the precipitation of the iron. The print is afterwards washed with an ammoniacal solution of sodium citrate in order to remove both the iron and the silver salts (see this Journal, 9, 113-414).

Specially prepared paper coated with ferric salts is now on the market, and the developing solution recommended contains silver nitrate, 50 grains, sodium citrate, 1 oz., potassium dichromate, 1 grain, water, 10 oz., ammonia solution 880, 30 minims. The quantity of ammonia here stated leaves a large proportion of the silver citrate undissolved. My experience is that better results are obtained with a solution containing silver nitrate, 1 part, sodium citrate, 10 parts, water up to 100 parts, ammonia, *quant. suff.* The silver nitrate is dissolved in five or six parts of water and carefully mixed with ammonia until the precipitate is just redissolved, and the solution is poured into a solution of the sodium citrate in about 80 parts of water and the mixture is diluted to 100 parts. A slight precipitate of silver citrate will form and is filtered off. The developing solution and the solutions used for washing the print should be kept in the dark as much as possible. With the present commercial paper the use of developing solutions containing potassium oxalate or borax in place of sodium citrate produces no noteworthy difference in the colour of the image. It is stated that the addition of a small quantity of potassium dichromate to the developer gives greater contrasts in the resulting print, but I was not able to observe any such result.

The image formed consists of metallic silver, or at any rate behaves exactly like metallic silver with various reagents. It is bleached by solutions of mercuric chloride or cupric bromide, but can be redeveloped by treatment with any ordinary developing solution after the excess of the mercuric or cupric salt has been washed out. The image bleached with mercuric chloride or bromide can be intensified by treatment with a solution of potassium silver cyanide and probably by other methods also.

The image is not appreciably affected by exposure for 48 hours to the products of the combustion of sulphur in air, nor by immersion for the same length of time in a solution of sulphurous acid. A solution of hydrogen sulphide produces a slight change in the colour of the image, but has no other effect. Ammonium sulphide in dilute solution changes the colour from black to brown without any loss of detail, and with only a slight loss of intensity. The brown colour is not unpleasant, and is very suitable for certain subjects. There is no reason to doubt the permanence of the images when exposed to ordinary atmospheric influences.

The colour of the image with the commercial paper is not a pure black, but has a tendency towards a slightly bluish tinge. This, however, will probably be remedied when further experience has been gained with the process, and though at present kallitype cannot be regarded as equal to the much older platinotype, it is considerably cheaper, and is capable of giving very fine results with good negatives of suitable subjects.

MR. E. C. A. FAWSITT IN THE CHAIR.

ON DESTRUCTIVE DISTILLATION.

BY EDMUND J. MILLS, D.Sc., F.R.S., AND T. O. McMILLAN.

PART II.

It has been shown in a previous Part (this Journal, 1885, 325) that the destructive distillation of various organic substances is an act of very definite character; and that in various instances, including coal, for example, the distribution of the original material is based on a C_{30} unit. The investigation was, however, incomplete, because the above results were only established for gas and tar taken together. The main object of the present research is to prove that they are true for the gas and tar separately.

The coal employed was a Scottish bituminous coal (Balquhatstone), much in request for household purposes in the West of Scotland. It was very carefully sampled for analysis. Total sulphur was determined by Nakamura's process (J. Chem. Soc. 1879, 787). Pit water was determined at 100° in a current of purified dry coal gas. There was practically no additional loss up to 130° . The organic analysis was carried out in a mixture of plumbic chromate and cupric oxide, oxygen being used at the last. The percentage composition was as follows:—

Carbon	82.54
Hydrogen	4.88
Oxygen	5.58
"Pit water"	2.52
Nitrogen	1.75
Sulphur	0.77
Ash	1.96
	100.00

The sample contained sulphate corresponding to 0.05 per cent. of sulphur.

The carbon, hydrogen, and oxygen have the relation $C_{18}H_{12}O$:—

	Found.	Calculated.
Carbon	88.75	88.53
Hydrogen	5.25	4.91
Oxygen	6.00	6.56
	100.00	100.00

It may be of interest to compare this composition with others similarly worked out:—

Yorkshire and Durham	$C_{24}H_{14}O$
Balquhatstone	$C_{15}H_{12}O$
Boghead	$C_{12}H_{10}O$
Average cannel	$C_{12}H_{12}O$
Heywood gas cannel	$C_9H_{12}O$
Good average Scotch shale	$C_8H_{10}O$

[Mills's Destructive Distillation, pp. 39, 40, 56.]

Low Temperature Distillation.

The coal was crushed until it would pass fairly through a sieve having six holes to the inch. The portion of this unable to traverse a sieve having eight holes to the inch was employed for the destructive distillations. The fragments distilled had an average diameter of $3\frac{1}{2}$ millimetres. The nature of the apparatus employed will be sufficiently understood by reference to the following sketch:—

The retort was a piece of hard glass, and contained 10 grms. of coal.

The source of heat was a Fletcher burner, gradually raised. The uncorrected results were as follows:—

	Per Cent.
Coke (free from ash), 3 experiments	73.32
Crude gas (1,500 cc, sp. gr. 1.89)
Water (including 2.52 pt water), 3 experiments	6.20
Tar	8.53

The gas was measured over water saturated with gas from a previous operation. Its specific gravity was determined with the effusimeter. The following is the composition of the gas, including air in the apparatus:—

	Vols.
"Pure" Methane	41.03
"Pure" Hydrogen	19.90
"Pure" $C_{18}H_{12}O$	1.54
Carbonic oxide	6.56
Nitrogen	27.51
Oxygen	5.99
Carbonic dioxide	0.83
Hydric sulphide	0.12
	103.78

The calculated specific gravity of the "pure" gas is 0.537.

If the "pure" gas only be considered, and the above volumes be converted into weights, the composition will be found to be:—

	Found.	$C_{30}H_{10}O_2$
Carbon	70.98	70.14
Hydrogen	19.91	20.51
Oxygen	9.11	9.35
	100.00	100.00

Thus the gas may be considered, as is probably usual for low temperature gas, to be mainly re-distributed methyl and water ($C_{30}H_{10}O_2 = 30 CH_4.3 H_2O.H_2$).

100 grms. of the pure organic matter of the coal give 6.927 grms. pure gas (= 3,580 cubic feet per ton).

The tar was analysed by combustion in a platinum boat, in front of which was a mixture of cupric oxide and

plumbic chromate. Oxygen was used when the tar began to burn with difficulty. The percentage composition was as follows:—

Carbon.....	50.92	Mean of 6 determinations.
Hydrogen.....	12.81	
Oxygen.....	24.60	
Nitrogen.....	1.19	
Sulphur.....	1.48	
	100.00	

On the usual assumption that the tar contains 0.5 per cent. of water, and neglecting nitrogen and sulphur, we have:—

	Found.	$C_{10}H_{12}O_2$
Carbon.....	61.88	62.05
Hydrogen.....	13.17	13.13
Nitrogen.....	24.95	24.82
	100.00	100.00

The tar may be regarded mainly as redistributed methylene and water [$C_{10}H_{12}O_2 = 30 CH_2 + 9 H_2O - H_2$].

Water was determined by removal with a pipette from the total weighed distillate, and then weighing the remainder.

The coke was set aside for analysis, but was found on analysis to have taken up so much water and oxygen from the air as to render the results unavailable.

The equality connecting the composition of the pure organic matter of Balgubastone coal with its products of destructive distillation at a low temperature may be written thus:—

	Found.	Calculated.
Coke.....	78.84	79.79
Tar (- 0.042 water) ...	8.51	8.49
Gas.....	7.15	7.51
Water (+ 0.042 in tar) ..	4.61	4.21
	99.11	100.00

We have thus reached a very simple result. About nine-tenths of the carbon of the organic matter has been converted into coke; the rest has been divided equally between the tar and the gas.

High Temperature Distillation.

The apparatus employed is illustrated in the following sketch. It consisted of a tube and furnace of malleable iron, followed by a Wolff's bottle, a coil surrounded by ice, and a Pepys' gas-holder.

The tube having been heated by charcoal to a point considerably above redness, the plug at its open end was momentarily removed, and an iron spoon inserted containing 30 grms. of coal, in pieces of the same size as employed for the low temperature distillation. The spoon was about 18 in. long, $\frac{3}{8}$ in. in diameter, and $\frac{1}{8}$ in. thick. Immediately after its insertion the plug was luted and replaced: gas came off directly afterwards. This apparatus is very convenient for determining the gas given off by coal at a high temperature. We are not, however, acquainted with any laboratory method of determining directly the tar or water: but it may be assumed, in accordance with well-known facts, that the latter is practically the same in amount both at low and high temperatures. Hence the tar may approximately be determined by difference. The coke was determined in a platinum crucible,—a method which gives the same result as in working on a large scale. The uncorrected results were:—

Coke (free from ash).....	67.15 per cent.
Gas.....	28.33 cc. (sp. gr. 457)

The following is the composition of the gas:—

	Vols.
"Pure" Methane.....	37.31
gas. { Hydrogen.....	44.58
{ $C_{3-9}H_{10-107}$	2.59
{ Carbonic oxide.....	9.82
{ Nitrogen.....	5.82
{ Oxygen.....	0.76
{ Carbene dioxide.....	0.78
{ Hydric sulphide.....	1.04
	102.20

The calculated specific gravity of the "pure" gas is 0.403.

If the pure gas only be regarded, and the above volumes be converted into weights, the composition will be found to be:—

	Found.	$C_{30}H_{120}O_5$
Carbon.....	63.01	63.16
Hydrogen.....	22.78	22.81
Oxygen.....	14.21	14.03
	100.00	100.00

Thus the gas may be considered, as is probably usual for high temperature gas, to be mainly redistributed marsh-gas and water [$C_{30}H_{120}O_5 = 30 CH_4 + 5 H_2O$].

100 grms. of the pure organic matter of the coal, give 14.65 grms. pure gas under "high" temperature conditions (— 10,082 cubic feet per ton).

On account of some tar being carried off into the gas holder during the generation of gas, we could not directly determine it. We, however, obtained the following results in analysing the tar:—

Carbon.....	75.75	5 experiments.
Hydrogen.....	8.29	
Oxygen.....	13.13	
Nitrogen.....	1.66	
Sulphur.....	1.17	
	100.00	

On the assumption that the tar contains 0.5 per cent. of water, and neglecting nitrogen and sulphur, we have:—

	Found.	$C_{30}H_{120}O_5$
Carbon.....	77.96	77.59
Hydrogen.....	8.53	8.62
Oxygen.....	13.51	13.79
	100.00	100.00

The composition, similarly calculated, of a sample of London tar, and given in Part I., was $C_{21}H_{23}O_3$, which differs little from what has been above recorded. Our tar may be regarded as mainly redistributed methinyl and water [$C_{30}H_{40}O_4 = 30 CH + 4 H_2O + H_2$].

The observations we had already made in connexion with low temperature coke having convinced us that the whole subject of the composition of coke requires fresh investigation, we did not analyse our high temperature product.

The equality connecting the composition of the pure organic matter of our coal with its destructive distillation at a high temperature may be written thus:—

—	Found.	Calculated.
Coke	72.20	71.15
[Tar	6.38]	6.34
Gas	14.65	15.58
[Water.....	4.01]	3.93
	97.24	100.00

Under the column "Found" we have placed, as previously indicated, the water of the low temperature distillation. The tar is calculated by assuming also the losses of the low temperature analysis.

We have thus arrived at a very simple result. About five-sixths of the carbon of the organic matter has been converted into coke; the rest has been divided in the proportion of 1:2 between the tar and gas.

Considering comparatively the low and high temperature distillations of the same organic matter, it is evident that the high temperature volatiles in gas twice as much carbon as the low temperature does.

These results are so simple and so distinct that we are disposed to regard them as probably normal conditions in the low and high temperature industries respectively.

Among minor inferences from our work, we desire to call attention to the fact that low temperature tar is much more oxidised than high temperature tar, the contrary being necessarily true for the gas.

Our best thanks are due to Messrs. Hamilton, Buchanan, and Baird for valuable assistance in this investigation.

THE SCRUBBING OF GASES.

PROFESSOR MILLS then made a verbal communication "On the Scrubbing of Gases."

In order to determine the amount of matter that can be removed from a gas, *e.g.*, coal gas, by scrubbing, the dry gas is passed through a succession of U-tubes of exactly the same pattern, and each about half filled with the same weight of pumice of uniform grain, saturated with heavy lubricating oil. It is convenient to cool the gas and U-tubes with ice. After a suitable time has elapsed, tube I. (nearest the supply) will be found to have absorbed a certain weight *a* of hydrocarbon; tube II. will contain less, say, *r a*; tube III. will contain less, say, *r (r a) = r² a*; &c., &c. Three tubes will usually be found sufficient. The

total amount of hydrocarbon that would have been absorbed, from the volume of gas under experiment, by an infinite number of such tubes, is $\frac{a}{1-r}$.

It is obvious that tube I. should not be allowed to become saturated, and that the gas to be scrubbed should not be saturated with the various matters to be removed.

Obituary.

EDWARD WILLIAM PARNELL.

A MEMBER OF THE SOCIETY OF CHEMICAL INDUSTRY.

EDWARD WILLIAM PARNELL was born in 1848, in St. Helen's, Lancashire, where his father, Edward Andrew Parnell, was then carrying on chemical manufactures in partnership with William Henry Bahnam. After receiving a general education at various schools, including the Wigan and Bristol Grammar Schools, he applied himself to the study of chemistry as a profession, under the superintendence of his father, who then resided in Swansea. In 1867 he went to Wiesbaden, and became a laboratory pupil of the renowned analyst, Professor Fresenius. At the completion of his course, Professor Fresenius invited him to become his assistant; but Mr. Parnell, intending to devote himself to technical chemistry, returned to England, and soon became engaged in the laboratory of the chemical works of the Runcorn Soap and Alkali Company. He afterwards became managing director of the Desoto Alkali Company, having works at Widnes for the manufacture chiefly of caustic soda. For a few years prior to his decease, he applied himself with great energy to carrying out the process of his invention known as the "Parnell and Simpson Alkali Process," the object of which is to conjoin and carry on unitedly the old Leblanc process with the ammonia-soda process; with production of soda-ash, caustic soda, bleaching powder, and sulphur. A paper, by Mr. Parnell, describing his process, which he read before the Liverpool Section of the Society of Chemical Industry, will be found in the Journal of the Society, Jan. 31, 1889 (No. 1, Vol. viii). Unfortunately, he did not live to see all the practical difficulties in some of the details of this ingenious and promising process surmounted.

An important improvement in the manufacture of caustic soda, introduced by Mr. E. W. Parnell, consisted in causticising under high pressure. A much stronger liquor is obtainable thereby than at ordinary pressure.

His uprightness, amiability, and unselfishness, brought him the esteem of all who knew him; and those who knew him best esteemed him most. He died in London on April 3rd, within a few days of the forty-third anniversary of his birth-day.

See pages 511—517.

PATENTS.

Improvements in and relating to Evaporating and Distilling Apparatus. J. Foster, Sunderland. Eng. Pat. 1309, March 19, 1890. 11d.

These improvements refer to the construction, arrangement, and combination of evaporating vessels by fitting them each with one or more divisions or compartments within the same outer shell, each compartment forming a separate evaporator and capable of working in combination with the other compartments either as single, double, or multiple effect. Several of these vessels may be arranged to work together and thus afford ready means for the installation of various-sized evaporating plant capable of convenient and quick adjustment for the work in hand. The system is applicable to both vertical and horizontal evaporators or distillers, several arrangements of which are indicated in the two sheets of drawings attached to the specification.—B.

An Improved Furnace or Heating Chamber for Conducting Chemical Operations. G. E. Davis and A. R. Davis, Manchester. Eng. Pat. 6433, April 28, 1890. 8d.

In this improved furnace the chemical operations can be performed, either with or without contact with the fuel gases, and the furnace may be fed and discharged automatically, and the speed of working regulated at will.

The furnace consists of an elongated tube, preferably oval in section, either fixed or made to revolve, and containing two or more removable longitudinal shafts, carrying creeper-blades. The shafts are placed at such a distance apart that the extremities of the creeper-blades of one shaft nearly touch the metal of the next, the pitch of the blades being such that those on one shaft nearly touch those of the next at some point in their revolution, by which arrangement they are kept free from deposits and incrustations. By suitable gearing the shafts may be made to revolve in the same or opposite direction, and the speed of revolution varied to suit the chemical substances under treatment. In certain processes two or more of these furnaces may be arranged at different levels, so that the lower one may be charged from that above. The furnace may be conveniently heated by a fire-place underneath. External air is excluded when necessary by sealing the openings, or by other means.—E. S.

Improvements in Appliances for Cooling or Heating and Filtering Oil and like Liquids. F. N. Mackay, London. Eng. Pat. 7696, May 17, 1890. 8d.

A JACKETED cylinder is fitted internally with rotating scrapers and oil circulators, and is supplied with means by which liquid ammonia or like substance is injected into

the jacket and allowed to evaporate therein, the gas evolved being led to a purifier; the main object being to cool the oil or liquid by direct application of a heat-absorbing liquid combined with direct application of the pressure necessary for filtration. Better results are said to be obtained and with greater economy. To effect this, six improvements in the apparatus are described, for details of which the specification must be consulted.—E. S.

Improvements in Means or Apparatus for Use in Producing or Separating Oxygen and Nitrogen Gases from Atmospheric Air, also applicable for Manufacturing other Gases. W. Cryer, London. Eng. Pat. 8752, June 6, 1890. 8d.

RETORTS are set in nests and "supported at their ends in a series of holes in plates or supports," and are surrounded by openwork rows of bricks or tiles. By this arrangement it is claimed that the destruction or sagging of the retorts consequent on local excessive temperature or want of adequate support is avoided, the bricks or tiles constituting moreover a reservoir of heat.

An alternative method of supporting the retorts consists in the use of pipes, through which water circulates and is used for the generation of steam or some similar purpose. Such pipes conveniently serve as runners on which the retorts may be readily drawn.—B. B.

Improvements in Apparatus for Evaporating, Concentrating, and Distilling Liquids. W. R. Watson and R. A. Robertson, Glasgow. Eng. Pat. 8790, June 7, 1890. 6d.

THE object of this invention is to simplify the construction of the apparatus described in Eng. Pat. 11,485 of 1888 (this Journal, 1889, 530), and so render it more easily packed for transport. This is done by forming the separating chambers into a column detached from the evaporators, with which they are connected by pipes.—E. S.

Improvements in the Manufacture of Tin, Iron, and other Metal Drums for carrying Oils and other Liquids. G. Cox, London. Eng. Pat. 9685, June 23, 1890. 6d.

IN A one edge, the lid is dished outwards from the inside around the bung-hole, and on to the part thus raised a nozzle to receive the bung is so braced as to leave no internal projection. This allows free outflow of the liquid, whilst it also adds strength to the bung-hole.—E. S.

Improvements in Cocks for Mixing Gas and Air. R. Gochde, Hanover, Prussia. Eng. Pat. 10,698, July 10, 1890. 8d.

THE invention relates to the construction of cocks by which a mixture of gas and air, the latter at ordinary atmospheric pressure or under compression, is produced for feeding burners of heating apparatus, the object being to prevent explosions occurring in the cocks and burners and their connections, both when the mixture issuing from the burners is lit and when it is turned off. In order to understand the construction of the cock it will be necessary to consult the drawing attached to the specification.—E. S.

An Improved Construction of Kilo for Drying Moist Materials. G. A. Hart, Hull. Eng. Pat. 12,897, August 16, 1890. 6d.

THE material is placed on a horizontal revolving table beneath which are one or more fire-places, the whole being arranged in a dome-shaped circular building. Scrapers are suitably placed above the table for turning over the material and for delivering it, when required, through an exit.—H. K. T.

* Any of these specifications may be obtained by post, by remitting the cost price, plus postage, to Mr. H. Reader Luck, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. The amount of postage may be calculated as follows:—

If the price does not exceed 8d.	1d.
Above 8d., and not exceeding 1s. 0d.	1d.
" 1s. 6d., " " 2s. 4d.	1½d.
" 2s. 4d., " " 3s. 6d.	2d.

Improvements in Centrifugal Apparatus for Treating Molten Material. O. B. Peck, Chicago, U.S.A. Eng. Pat. 15,343, September 27, 1890. By Internat. Conv. March 3, 1890. 8d.

See under X., page 552.

Improvements relating to Centrifugal Apparatus for Treating Molten Material. O. B. Peck, Chicago, U.S.A. Eng. Pat. 15,348, September 27, 1890. By Internat. Conv. March 3, 1890. 8d.

See under X., page 552.

Improvements relating to Centrifugal Apparatus for Treating Molten Material, and to Means for Removing the said Material from such Apparatus. O. B. Peck, Chicago, U.S.A. Eng. Pat. 15,349, September 27, 1890. By Internat. Conv. March 3, 1890. 6d.

See under X., page 553.

Improvements in or relating to Gas Compressing Pumps and their Application to Refrigerating Apparatus. C. G. Mayer, New York, U.S.A. Eng. Pat. 85, January 2, 1891. 8d.

This patent deals principally with improvements in the details of pumps used with refrigerating apparatus, in which a gas is alternately condensed by compression and volatilised, the heat required for vaporisation being taken up from the circulating liquid. Three sheets of drawings show a general arrangement of the apparatus and details of the compressing gas pump, and there are 22 claims, of which the more important seem to be one for temporarily equalising the pressure on both sides of the piston to facilitate the work at starting, and one for cooling the oil used for lubricating the piston-rod gland.—B.

Apparatus for Distilling and Rectifying. A. G. Burkhardt, Stuttgart, and G. Schude, Hohenheim, Germany. Eng. Pat. 1214, January 23, 1891. 6d.

THE apparatus is formed of two concentric cylinders, the walls of which are spirally corrugated. A pipe passes up the centre of the apparatus, the space between it and the inner cylinder forming a steam jacket. In practice two of these appliances are superimposed. The liquid to be distilled is passed up the central tube of the lower portion of the apparatus, and overflowing, spreads over the outside of the inner cylinder, which is heated by means of steam, as described above. The volatile portion of the liquor finds its way into the space between the outer and inner cylinders of the upper portion of the combined apparatus, where it undergoes rectification. For details and drawings of the apparatus, the original specification must be consulted.

—H. T. P.

Improvements in Filtering Apparatus. H. H. Lake, London. From E. M. Knight, San Francisco, U.S.A. Eng. Pat. 1509, January 27, 1891. 8d.

THE filter consists of two separate chambers, one above the other, the upper one standing on the rim of the lower one. This latter forms the storage and delivery chamber. The bottom of the upper chamber is fitted with two wire screens, having asbestos cloth between them. On the upper screen, a paste made of finely-powdered charcoal and water is placed, the whole being properly secured in its place. Resting on this a second and similar screen, but without the paste, is placed, which can be lifted off and on by a handle. The object of this second screen is to prevent the water when poured on from washing away the paste on the lower screen, whilst it also serves to receive any coarse sediment which may be in the water, and prevent its passing readily through upon the filtering medium below.

—E. S.

Improvements in Filtering Apparatus. H. H. Lake, London. From E. M. Knight, San Francisco, U.S.A. Eng. Pat. 1521, January 27, 1891. 11d.

A SERIES of tanks, which can be used independently or together, is supported and secured in a battery of exterior bracing frames. In the interior of each tank is a filter frame, the sides of which are formed of finely-perforated wire-cloth, upon which is spread asbestos, to support the filter bed, which is formed of a coating of finely-powdered charcoal, made into a paste with water, and brushed into the interstices of the wire-cloth, until a sufficient thickness has been applied.

For further details of construction and mode of working the specification, and three sheets of drawings attached, must be consulted. There are 11 claims.—E. S.

Improvements in the Method of and Apparatus for Forcing Semi-Fluids into Filter Presses. S. H. Johnson and C. C. Hutchinson, Stratford. Eng. Pat. 3004, February 19, 1891. 8d.

IN filter presses of the usual construction, the amount of sludge which can pass through the press gradually diminishes as the pressure increases during each operation, and, in order to prevent overstraining, the pumps employed must either allow part of the sludge to escape through a relief valve, or they must be worked at greatly reduced speed towards the end. In the former case a loss of power results, whilst in the latter the valves and passages are stopped up with the fibrous material, and the proper action of the pumps is impeded.

The patentees avoid these inconveniences by causing the pumps to work intermittently, but always at their full speed, and to stop automatically every time the full pressure has been reached. When the pressure has fallen again by a predetermined amount, a regulator comes into action automatically, to open the steam-valve of the pumps, and this is repeated until the press is quite filled. Details of the regulator, and a complete arrangement of the plant, are shown in the drawings. There are two claims.—B.

A New or Improved Method of and Apparatus or Machinery for Continuous Mechanical Distilling. S. Barber, London. Eng. Pat. 3140, February 20, 1891. 8d.

THE apparatus consists of a combination of horizontal mixers and horizontal closed cylinders or stills with central revolving shafts and stirrers, for the purpose of mixing and automatically delivering certain solid substances, such as coal or coke, stones, shells, sand, cork, pulps, &c., whilst undergoing the process of distillation. Tars, oils, or acids may be injected into the mixer for distribution amongst the solid matter, whilst air, steam, or gases are admitted to the stills through nozzles entering from below, and the resulting gases or vapours drawn off from above. The mixer and stills deliver from one to the other automatically, and the solid materials are discharged at the end of the last still, ready for any further treatment, such as pressing into blocks, &c. The drawings accompanying the specification give a general idea of the arrangements of the apparatus, and are supported by five claims.—B.

Improvements in Apparatus for Automatically Changing the Direction of Flow of Currents of Fluids through Pipes or Passages. "The Brins Oxygen Company, Limited," and K. S. Murray, London. Eng. Pat. 4292, March 10, 1891. 8d.

THE improvements apply to part of apparatus previously described in Eng. Pat. 4955 of 1889, and consist in devices for the automatic reversal of valves with a view to the reversal of the flow of air or gases through pipes. The presence of the fluid in the pipes is made use of for producing the desired change, and for details, the specification and two sheets of drawings must be consulted.—B.

Improvements in Evaporators. R. Haddan, London. From I. W. Evans, Cleveland, U.S.A. Eng. Pat. 5555, March 31, 1891. 8d.

In the naphtha process of extracting oil from seeds, the seeds, after having been ground, are placed in percolators

filled with naphtha, which extracts the oil, and is afterwards separated therefrom by evaporation and condensation. Quantities of, say 1,000 bushels, of meal, and perhaps 150 barrels of naphtha, may be treated in one percolation at a time, and several of these may be working in conjunction,

IMPROVEMENTS IN EVAPORATORS.

and the evaporator must, therefore, be of ample size and efficiency to enable its work to be done with despatch.

The invention refers to the construction of an improved evaporator with that point kept in view, the naphtha being evaporated at comparatively low heat. The accompanying illustrations show the apparatus in longitudinal and cross sections, and will be clear from the following references, viz. :—

A is a rectangular box or container, preferably made of sheet iron with circular top, having an opening at one side extending the full length of the vessel. To the flanges of this opening are secured the lengthening piece A^1 and cover plate A^2 with outlets a and a^1 for the naphtha vapours. The interior is heated by the steam coil B and the perforated steam pipes B^1 , from the latter of which the steam can be cut off by the valve B^2 without affecting the remainder. Above the steam pipes are fitted agitators, consisting of hollow shafts C with hollow prongs C^1 , into which steam can be admitted through the tap C^2 , for the purpose of keeping them at the proper temperature. In the upper part of the vessel the hollow troughs D heated by steam still further aid evaporation, whilst their shape facilitates the collection of any naphtha condensed overhead. E is a vacuum valve, for protection against a collapse of the vessel on cooling; F, glass gauge; I, glass lights; J, inlet pipe for the compound; and K, outlet for the purified oil; L, well for ascertaining the temperature, and there are man-holes and other usual mountings. The specification covers six claims.

—B.

II.—FUEL, GAS, AND LIGHT.

The Scrubbing of Gases. E. J. Mills.

See page 527.

PATENTS.

Improvements in the Method of and Apparatus employed in the Manufacture of Coal-Gas and of Compounds of Ammonia. T. Holgate, Halifax. Eng. Pat. 3684, March 8, 1890. *Sd.*

THE improved apparatus is a suitable arrangement of various stills of any approved form, whereby the waste heat generated in the preparation of ammonia from ammoniacal liquor and in the purification of crude ammoniacal liquor (and in the manufacture of coal-gas) can be utilised. The apparatus consists of two parts, one for the preparation of ammonia for making sulphate, the other for the partial purification of crude ammoniacal liquor (for use in purifying coal-gas), the two parts and processes being worked in conjunction with one another.

The apparatus for preparing ammonia consists of a still A, in which the crude liquor, previously warmed in D, is heated to drive off the free ammonia, &c.; the gases pass into an ordinary saturator, the liquor being conveyed to a second vessel B, placed below A, and there agitated with lime; the mixture is then passed into another still C, and heated to drive off the rest of the ammonia. The spent liquor from C is passed into a still D, and its heat is utilised for warming the cool ammoniacal liquor before it passes into A.

The other part of the apparatus consists of a vessel E, in which ammoniacal liquor previously warmed by passing through the vessels G, F, or H, F, is being heated to expel sulphuretted hydrogen and carbon dioxide; these gases

APPARATUS FOR TREATING AMMONIACAL LIQUOR.

pass to the saturator, and the purified liquor runs into a cooler G placed below where its waste heat is utilised for raising the temperature of crude ammoniacal liquor before it passes through F into E. Situated between E and G is a vessel F, which receives hot waste gases from the saturator and in which ammoniacal liquor, already warmed in G, or in H, is still further heated. The waste gases from F are conducted through a still H, where crude ammoniacal liquor is heated before it passes into F and E, and then to a "Claus kiln," sulphuric acid plant, or oxide of iron purifier.

—F. S. K.

Improvements in Coke Ovens, and in the Method of Using the Same. E. Edwards, London. From F. Strohmer, Dresden, Germany. Eng. Pat. 4457, March 21, 1890. *Sd.*

IN this invention it is proposed to use trucks for coking in. The coal is carefully laid and rammed down in the trucks, four of which are used. The trucks are introduced into a vaulted fire-brick coking oven, suitably arranged, and to which air has free access from the bottom. After coking, a fresh truck is pushed in at one end and so pushes out the one furthest away and most coked. The doors are closed and coking resumed.

It is claimed that this furnace and mode of operation will be useful for glass or smelting furnaces, pottery kilns, and such like.—D. A. S.

Improvements in Apparatus for Burning Hydrocarbon Oil as Fuel. H. H. Lake, London. From J. P. Swift, Woods Holl, U. S. A. Eng. Pat. 6502, April 28, 1890. 8d.

THIS is an apparatus in which petroleum or other liquid hydrocarbons are used for heating steam boilers or for similar purposes. The hydrocarbon is fed through C into a trough B, which may be lined with asbestos or similar material. The hydrocarbon is partially burnt and volatilised by a current of air entering through a. The flame so produced passes through D, and is urged onwards and burnt by a current of air passing through E. The tube F serves to keep together and thoroughly mingle the air and hydrocarbon flame. In order to prevent the

APPARATUS FOR BURNING HYDROCARBONS.

deposition of carbon on D and in the tube F, air is admitted through tubes surrounding the combustion chamber A, and through a side-tube H into F. The various air apertures are fitted with dampers.—H. K. T.

An Improved Process for the Manufacture of Illuminating Gas, and Apparatus therefor. R. C. Lindsay, Hampstead. Eng. Pat. 7252, May 9, 1890. 1s. 1d.

COAL, cannel, or other gas-making material is carbonised in retorts in the usual manner, and the gas, after being passed through condensers and washers, is led into an exhaustor. Before drawing the charge, steam is admitted, when carbonic oxide and hydrogen are produced at first, but later on, as the retort cools, carbonic acid and hydrogen are formed. The object of introducing steam is to prevent the coke from bursting into flame when the charge is being transferred to the water-gas retorts, this being a better method than damping with water, and also serving to keep the retorts free from carbon. The coke is then drawn, while still hot, and placed in a second series of retorts, where it is treated with steam, previously superheated in small fireclay pipes. These retorts are arranged in batteries of two; in the first two the steam is decomposed, forming principally carbonic acid and hydrogen; this mixture is then superheated in small fireclay pipes and passed into the second series of retorts, where the carbonic acid is converted into carbonic oxide. The water-gas produced in this way is now mixed with hydrogen, this gas being generated by passing superheated steam through vertical retorts, in which are fitted iron trays filled with spongy iron; the addition of hydrogen to the water-gas is necessary to keep down the percentage of carbonic oxide in the illuminating gas subsequently produced.

The purified gas obtained from the coal is forced back to the retort bench, and there divided into six or more jets, each of which passes into the end of a carburetter, drawing with it the water-gas from the water-gas retorts, and also a supply of heavy petroleum oil; the gaseous mixture obtained in this way is then forced by another jet

of coal-gas into a second carburetter, and so on, until the desired luminosity is obtained, and finally led away to coolers, scrubbers, &c., and stored in the usual manner.

All the retorts, of which there are four for carbonising, four for the production of water-gas, and two for the production of hydrogen, together with the superheating pipes and carburetters, are arranged in an oblong gas furnace fitted with regenerators; the gas employed for heating is a waste gas, taken hot from the hydrogen producers, which are worked alternately; this waste gas is generated by passing fixed water-gas through one of the hydrogen producers, the other being used in the meantime for making hydrogen; in this way the oxide of iron is reduced to metal and the producer is ready for use again.

There are six claims and five sheets of drawings.—F. S. K.

Apparatus for Automatically Delivering any Proportionate Quantity of Oxygen, Air, or other Gaseous Body or Bodies into Gas Purifiers or other Vessels, Pipes or Conduits, irrespective of any Pressure there may be in such Gas Purifiers or other Vessels. C. B. Newton, Shrewsbury. Eng. Pat. 7714, May 17, 1890. 1s. 1d.

THE air, oxygen, or other reagent is contained in, or pumped from an ordinary holder into a gas-holder, of which the side sheets are carried above the junction of the crown so as to form a tank on the top of the holder; this tank is filled with water, so as to give a greater pressure than in the purifier or other pipes, and is fitted with an adjustable overflow, so that by raising or lowering the water level the pressure can be regulated at will. An electric contact maker, so constructed as to prevent any danger arising from sparking, is placed in connexion with the station meter index and with an electro-magnet, the arrangement being such that when a certain quantity of gas has passed through the meter the circuit is momentarily closed; the electro-magnet then attracts an armature, and certain valves, through which the air or other reagent is supplied, are thereby opened. The air, or oxygen, on its way to the purifier passes through a meter, which, by means of a suitable mechanical arrangement, shuts the valves again when the desired quantity has been admitted; the gas then passes through one or more regulating valves, worked by hand, by means of which the time occupied in passing can be lengthened or shortened as required, and then through a governor, which is so constructed as to maintain a constant difference of pressure between the inlet and outlet of the meter or regulating valves.

The same object may be accomplished by connecting the drum spindle of the station meter with that of the reagent meter. Sufficient pressure is then put on the reagent meter to drive it faster than the station meter, but, by means of a pawl and a projecting pin, the former is prevented from moving faster than the latter, and so the required percentage of gas passes into the purifiers or pipes; the reagent meter is not geared directly to the station meter, nor is it bound to revolve by the action of the latter, but rather follows it by reason of the pressure of the gas.—F. S. K.

Improvements in Apparatus for the Conversion of Solid into Gaseous Fuel and its Purification. B. C. Sykes and G. Blamires, Cleckheaton. Eng. Pat. 7830, May 20, 1890. 8d.

THE apparatus patented is a gas producer with an internal chamber for the partial combustion of the fuel, surrounded by an annular space filled with water, and surmounted by a steam space. The gases generated are caused to pass down vertical tubes placed in the annular water space, and to escape through the water, depositing tar and ammoniacal salts and converting the water into steam in so doing. The mixed gases and steam are "used to actuate a non-condensing engine," and then passed through a condenser where water is the cooling medium, and thence into one which is cooled by air, and finally pumped by compressors into the burning chamber. It is claimed that the process of condensation is "truly regenerative," that "any amount of temperature may be obtained," and that "the whole of the

nitrogen in the fuel, and possibly from the high temperature developed, and the high pressure employed, some of the nitrogen of the air will be converted into ammonia or cyanogen."—B. B.

A Process and Apparatus for the Manufacture of Illuminating Gas. S. Pitt, Sutton. From E. J. Jerzmanowski, New York, U.S.A. Eng. Pat. 8535, June 2, 1890. 8d.

Two fireclay retorts, each of which consists of a horizontal portion and three vertical portions, are filled with limestone, containing preferably some clay, and heated by a furnace until the limestone is converted into lime. Steam and oil are then forced into the horizontal portion of the retort, through a long perforated pipe, and there converted into illuminating gas; this gas, which contains also a small percentage of carbonic oxide and carbonic acid, passes through the vertical portions of the retort, where the illuminant is fixed, and is then led off to the hydraulic main. The gas is tested at frequent intervals and the admission of oil regulated accordingly.—F. S. K.

An Oil Flame Furnace. The Lucigen Light Company, Limited, and T. M. Jarman, Westminster. Eng. Pat. 9181, June 13, 1890. 6d.

The furnace may be portable, in which case it is placed on a wheeled truck, or stationary, but the essential parts are the same. They consist of a firebrick body with flue and chimney constituting the furnace proper, and a burner which is placed upon the top of the furnace and is directed downwards into it. The burner consists of an annular trough containing oil which is supplied from an adjacent tank, the flow being regulated by a float valve and capable of being cut off altogether when required, and of a nozzle for supplying superheated steam to drive the flame of the burning oil downwards into the furnace. This nozzle or jet is supplied from an annular boiler surrounding the mouth of the burner where it enters the furnace connected with a coil of pipe in the upper part of the burner serving as a superheater. Water for the boiler and superheater is supplied from a closed-in reservoir provided with a hand pump for compressing the air above the water, and thereby expelling it in a steady stream. On starting the furnace the oil is lighted in the trough and burns with its flame directed upwards until the water in the coil is converted into steam and begins to supply the jet. Upon this happening the boiler comes into play and continues the supply of steam to the coil which now acts as a superheater. A cap covering the burner is put on and the running continues automatically, air being drawn in through holes in the cap.—B. B.

Improvements in the Treatment of Liquid Hydrocarbons. J. H. W. Stringfellow, Walthamstow. Eng. Pat. 11,832, September 19, 1890. 6d.

See under III., page 534.

Improvements in Gas Producers or Generators. A. Dauber, Bochum, Germany. Eng. Pat. 20,002, December 8, 1890. 6d.

This is a furnace for the production of heating gas by the partial combustion of bituminous slate, turf, and other inferior solid fuels either alone or in conjunction with paraffin, tar, residues from oil works, or coal dust. The solid fuel is placed in a shaft having the shape of an inverted cone, and is burnt by a downward current of air, the gaseous products being drawn off through gratings at the lower extremities. Blast blowpipes conveying hot air or superheated steam and hydrocarbons or coal dust are inserted in the sides of the shaft and also in its central axis in order to assist the combustion. The clinker falls into a sump at the bottom of the shaft.—H. K. T.

Improved Method of and Apparatus for Treating the Smoke of Factory and other Chimneys for the Purpose of Rendering the same Innocuous. E. R. Sawley, Bristol. Eng. Pat. 489, January 10, 1891. 8d.

A JET of steam is directed across a chimney at any convenient height up the stack, the outlet from which it issues being either a continuous slot in a metal box or trough, or a perforated pipe extending half round the periphery of the chimney. The steam passes into a receiver which may be jacketed with cold water, and in this the impurities from the smoke are caught and allowed to fall into any suitable receptacle, the pipe leading down to which may be water-sealed. An alternative plan consists in the use of a jet not blowing across the chimney, but exhausting the smoke out of the chimney, the collecting arrangements being, however, the same. In this case a damper above the point of aspiration may be provided as an additional means of control. The apparatus may be fitted to the funnels of locomotive and stationary engines.—B. B.

Improvements in Methods of Generating Heating and Lighting Gases from Liquid and Solid Hydrocarbons, and in Apparatus therefor. B. H. Thwaite, Liverpool. Eng. Pat. 971, January 20, 1891. 1s. 1d.

This invention relates partly to improvements in former inventions (compare this Journal, 1890, 163, and 1891, 242) and has for its object the improvements in the methods and apparatus for the production of oil-gas and water-gas simultaneously.

Two vessels or chambers are connected together above by a refractory lined conduit, and each is provided at the upper part with an annular cavity, filled with open brickwork, so as to provide a large heating surface. Each vessel is provided further with an air inlet arrangement for supplying air requisite for the combustion of part of the gas produced; this combustion takes place immediately above the fuel, thus heating the open brickwork of a temperature necessary for the volatilisation and fixation of the liquid hydrocarbon, which is injected with steam. Each of the air inlets has a gas ignition flame, which is always kept burning in such a way that the flame covers the opening; this arrangement serves to ignite the combustible gas at intervals, as required, without explosion.

There are eleven claims and four sheets of drawings.

—F. S. K.

Improvements in Apparatus for use in the Manufacture of Gas. J. Price, Coleshill. Eng. Pat. 1560, January 28, 1891. 8d.

INSTEAD of putting the hydraulic main over the retort benches it is placed in a convenient position in the front of them, and the ascension pipe enters the main vertically from underneath, the end projecting just above the water line; the advantages of this arrangement are, firstly, there is considerable saving in the length of pipe required; secondly, the use of arch-pipes is obviated; and thirdly, the direct action of heat from the retort benches on the tar, &c., in the main is avoided.

A cover or inverted thimble of black-tin or iron is placed over the open end of the ascension pipe and dipping into the liquor in the main; this cover is perforated and moveable vertically, so that when gas is escaping from the ascension pipe the cover is lifted to the water level, and in this way the back pressure is taken off the retorts. Instead of allowing the cover to lift automatically it may be raised if desired, or lowered into the liquor with a lever, or fixed by a screw; in the latter case it then acts as a washer.

The tar is drawn off from the bottom of the hydraulic main; a tank containing ammonia-water is placed above the level of the main so that it may be kept cool by a flow of liquor.—F. S. K.

Improvements in Apparatus for Carburetting Air. G. Hargreaves, J. P. Seranton, and E. W. Porter, Detroit, U.S.A. Eng. Pat. 2145, February 5, 1891. *8d.*

THE object of the patent is to secure an automatic regulation of the oil and air used in making carburetted air for lighting purposes, so that the supply is always controlled by the demand.

This end is secured by the use of an air pump driven by a motor consisting of a drum, round which is wrapped a cord attached by tackle to a falling weight, the pump being of the same type as the wet gas meters used for locally increasing the pressure of the gas supply for manufacturing purposes. The motor is only in action when carburetted air is being burnt, and the rotation of the pump proceeds at the rate determined by the consumption. At the same time the reservoir containing the oil used for carburetting is put under pressure, and the flow of oil from it to the carburettor is controlled by a plunger pump and needle valves actuated by a shaft connected by gearing with the driving drum.

The carburettor consists of a series of conical discs with their apices alternately turned up and down, and provided with perforations disposed alternately at the centres and edges of the cones; the oil is allowed to trickle from top to bottom.

It is claimed that the reservoir of oil being maintained at a fixed pressure, its separation into lighter and heavier fractions is avoided.—B. B.

Improvements in Apparatus for Measuring or Delivering Air or other Gases, and for Mixing Air with other Gases in Definite Uniform Proportions, and Delivering the Mixture under a Definite Uniform Pressure. W. P. Thompson, Liverpool. From J. Taylor, New York, U.S.A. Eng. Pat. 2427, February 10, 1891. *8d.*

THE inventor uses two drums, constructed very much like those employed in liquid gas meters, which are immersed in water or some other suitable liquid to some distance above the middle of their height. The drums are built each in two compartments longitudinally, one part receiving the gas from the outside through an elbow pipe, the mouth of which reaches above the water level. The other part of the drum is sub-divided, by diaphragms, into a number of longitudinal spiral partitions with radial openings at each end which, on the rotation of the drum, dip alternately under the water, and allow a measured quantity of gas to pass from the first compartment into the vessel within which the two drums are enclosed. The said elbow pipes protrude at the other end, and have motion imparted to them in any desired way, their relative speeds being controlled by differential gearing. Any predetermined mixture of gases can be brought about by speeding the drums accordingly; and the apparatus has been more particularly designed for mixing air and hydrocarbon gas in fixed proportions for illuminating or heating purposes. An additional mixing chamber is also provided for the more complete mixing of the gases before they leave the vessel. There are three sheets of drawings and three claims.—B.

Improvements in Apparatus for the Manufacture of Gas from Petroleum Oil. W. P. Thompson, Liverpool. From G. S. Sanford, Mount Clemens, U.S.A. Eng. Pat. 2889, February 17, 1891. *6d.*

THE apparatus is for producing gas, either for illuminating or for heating purposes, from petroleum oil. It consists essentially of (1) a retort in which a mixture of steam, air, and petroleum oil is raised to a high temperature and thus converted into a fixed gas; (2) a mixer, in which the oil is thoroughly mixed with steam and air, and which is provided with suitable valves for regulating the proportions of the three ingredients; (3) an oil burner, of the same construction as the mixer, for heating the retort; and (4) apparatus for washing, purifying, and storing the gas produced.—F. S. K.

Improvements in the Manufacture of Coal Briquets. H. H. Lake, London. From G. A. Purbeck, New York, U.S.A. Eng. Pat. 2900, February 17, 1891. *4d.*

COAL-DUST, saw-dust, or other organic waste is mixed with a solution containing about 1 per cent. of dry bi- or tri-silicate of potash or soda, or a mixture of both, the specific gravity ranging from 30 to 65 B., and is then pressed into blocks and dried. Nitrates or permanganates may be added to assist combustion.—H. K. T.

PATENTS.

Improvements in the Destructive Distillation of Mineral Oils, and in Apparatus therefor. J. Laing, Edinburgh. Eng. Pat. 1120, March 17, 1890. Second Edition. *8d.*

MINERAL oils are cracked by distillation in a long cylindrical boiler divided into compartments by divisions reaching nearly to the bottom, and provided with exit tubes, condensers, and return tubes, so that the product of distillation from the compartment at the furnace end of the boiler may be condensed and drop into the next compartment, and so on, while the product of distillation from the compartment at the end of the boiler remote from the furnace passes off finally, and is condensed and collected in the ordinary manner. The temperature of the boiler is regulated by the opening or closing of dampers in flues running beneath it from end to end, the furnace gases being also capable of diversion without traversing the whole system.

The last compartment may be cooled, as to its outer side, by a water jacket; and is, moreover, provided with a draw-off tube for the pitchy residue left by the distillation of the oil in this manner, and with a pyrometer. The use of the latter is to allow of a temperature being attained and maintained, which has previously proved to yield the best results for the particular oil under treatment.

By this apparatus the production of lighter from heavier mineral oils is said to be successfully effected.—B. B.

Improvements in the Treatment of Liquid Hydrocarbons. J. H. W. Stringfellow, Walthamstow. Eng. Pat. 14,832, September 19, 1890. *6d.*

WITH a view principally to obviate the disadvantages attending the carriage and storage of liquid hydrocarbons, finely ground *quillaja saponaria* bark or similar saponifier is mixed with the liquid hydrocarbon under treatment. When water is added and an intimate mechanical mixture is ensured, solidification is set up by the water acting chemically upon the distributed particles of the saponifier and the whole mass quickly gelatinises. The solidified product does not "flow" when being burned; it may be re-liquefied by treatment with a small quantity of acid.

—K. E. M.

IV.—COLOURING MATTERS AND DYES.

Stability of Diazo-Compounds in Aqueous Solution.
R. Hirsch. Ber. 24, 324—326.

THE author has made experiments on the comparative stability of the diazo-compounds obtained from 9.3 grms. aniline, 10.7 grms. *o*-toluidine, 10.7 grms. *p*-toluidine, 12.1 grms. *m*-xylydine, and 17.3 grms. sulphathic acid. The amido-compounds were each dissolved in about 700 cc. water with the addition of 30 cc. hydrochloric acid, and diazotised with 7.2 grms. of sodium nitrate dissolved in sufficient water so that each product measured 1 litre. These solutions were then allowed to stand and from time to time the amount of diazo-product in each solution was determined by means of a standard solution of sodium naphtholsulphonate (Schäffer's salt) equal in strength to the freshly-prepared diazo-solutions. In each case 25 cc. of the standard naphthol-solution were taken and the amount of diazo-solution required to react with the naphthol-sulphonate contained therein was determined. The following table gives the number of cubic centimetres required, and it is evident that these must be in direct ratio to the decomposition:—

Hours.	Aniline.	<i>o</i> -Toluidine.	<i>p</i> -Toluidine.	<i>m</i> -Xylydine.	Sulphathic Acid.
1	26	32	25.5	27.5	25.5
2	26.5	40	25.6	30	25.5
3	29	50	25.5	33	25.5
4	30.5	77	26	37.5	25.5
5	31	94	27	43	26
6	34	112	27.5	46	26.5
24	50	265	27.8	70	27
240	50

It would appear from these results that a methyl-group in the para-position to the diazo-group imparts to the latter a remarkable degree of stability, whilst the reverse is the case with an orthomethyl-group.

Experiments are also tabulated showing the comparative stability of solutions of diazobenzene under different conditions of temperature, and also in the presence of sodium acetate, an excess of caustic soda, and of hydrochloric acid. The results show that the diazo-compound is rendered most stable by cold, that the addition of acid has a slight preservative effect, whilst the effect of sodium acetate or alkali is insignificant.—A. K. M.

A New Class of Fluorescent Dyes of the Quinoxaline Group. O. Fischer. Ber. 24, 719—723.

THE author has discovered a ready means of obtaining dihydroquinoxalines from orthodiamines and α -ketone alcohols.

When a mixture of benzoin and orthophenylenediamine in equal molecular proportions is heated in an open vessel at 160°—170° for three hours, *diphenylquinoxaline* is obtained as the main product; *dihydrodiphenylquinoxaline*—

is also formed in small quantity. On repeating the experiment in a sealed tube in order to avoid atmospheric oxidation, the latter substance formed the chief product, 60 per cent. of the theoretical yield being obtained, whilst but little diphenylquinoxaline was produced. Dihydrodiphenylquinoxaline forms dark yellow crystals, melts at 148°—149°, dissolves readily in benzene and in hot alcohol, more sparingly in ether and very sparingly in light petroleum; it is insoluble in water; the solutions in ether and benzene

show a beautiful yellowish-green fluorescence. It is a weak base, the salts which it forms with mineral acids and with acetic acid being decomposed by water.

Diphenyltolyl-tolquinoradine—

is similarly obtained from benzoin and orthamidoditolylamine. Its ethereal and benzene solutions also exhibit yellowish-green fluorescence.

In the same way benzoin and diphenyltriamidobenzene $[\text{NH}_2 : \text{NHC}_6\text{H}_3 : \text{NHC}_6\text{H}_5 = 1 : 2 : 4]$ yield—

whilst from benzoin and β -phenyl-*o*-naphthylenediamine the compound—

is produced. The former crystallises in greenish-yellow lustrous plates melting at 223°, and exhibits in its solutions (especially in alcohol and in benzene) a magnificent deep green fluorescence. The latter forms glistening plates or needles of an intense yellow colour and melting at 163°—164°, and its solutions in benzene, alcohol, and ether, exhibit a greenish-yellow fluorescence.—A. K. M.

Paramidocarbinols. O. and G. Fischer. Ber. 24, 723—729.

It has long been known that in the formation of the triphenylmethane colours by the action of an acid on the amido-carbinol, a molecule of water is split off between the OH group and a paramido group. In order to determine whether this reaction holds good for other amido-carbinols, the authors have prepared and experimented with paramidobenzylalcohol $\text{NH}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{CH}_2 \cdot \text{OH}$. This is obtained when paranitrobenzylacetate (Annalen, 147, 343) is reduced by means of stannous chloride and hydrochloric acid, the acetyl-group becoming displaced during the process. The resulting amido-carbinol crystallises in colourless plates of a silver lustre; it melts at 95°. Its hydrochloride is colourless and crystallises in long slender needles; when heated at 100°—120° it becomes yellow and the product in alcoholic solution will then dye silk. When the yellow salt is dissolved in water, the solution rapidly becomes colourless and the original colourless salt can be recovered. The authors consider that the production of the yellow colour is due to water being split off, thus giving rise to the formation of the compound—

They failed however to effect a quantitative conversion.

The hydrobromide behaves similarly to the above. The oxalate $\text{C}_7\text{H}_9\text{NO} \cdot 2\text{C}_2\text{H}_2\text{O}_4$, acetyl derivative—

and the benzoyl-derivative—

are described.

When a mixture of *p*-amidobenzylalcohol and benzaldehyde in molecular proportions is heated at 100°, the condensation product $\text{C}_6\text{H}_5 \cdot \text{CH} : \text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{CH}_2\text{OH}$ is formed; it crystallises in needles melting at 95°. Analogous compounds are also obtained by condensation with salicylic aldehyde and with cinnamic aldehyde, the products melting respectively at 163° and 155°.

The authors find that the amidotriphenylmethane prepared by Fischer and Roser (Annalen, 206, 113 and 155) from

benzhydrol and aniline, and which Fischer and Frankel (Annalen, **241**, 362) afterwards stated to be orthamidotriphenylmethane is really a paramido-compound as was first assumed.—A. K. M.

Oxidation of Hydropyridine Bases. C. Schotten.
Ber. **24**, 772—775.

THE author has previously shown that the benzoyl-derivatives of hydropyridine bases, namely, piperidine and conine, are readily oxidised by potassium permanganate with formation of amido-acids of the fatty series (Ber. **21**, 2235), and he now proposes to make use of this reaction for determining the constitution of pyridine bases.

Conversion of Tetrahydroquinoline into Isatine.—Quinoline was converted into its tetrahydro-derivative by reduction with tin and hydrochloric acid (Ber. **16**, 728), and the product agitated with caustic soda and benzoylchloride. The benzoyltetrahydroquinoline obtained was then boiled with a solution of two and a half times its weight of potassium permanganate. The chief product is *benzoylisatinic acid*—

This is almost insoluble in water and readily soluble in alcohol; it melts at 188°. A product identical with this is obtained when isatine is boiled with dilute caustic soda and the cooled alkaline solution agitated with benzoylchloride.

When benzoylisatinic acid is heated above its melting point, it loses water and is converted into *benzoylisatin*. This crystallises from glacial acetic acid in yellow needles, and melts at about 206°.—A. K. M.

Hydroxyketone Colouring Matters. A New Dihydroxy-xanthone. C. Graebe and A. Eichengrün. Ber. **24**, 967—970.

THE authors are investigating some of the colouring matters belonging to the hydroxyketone group patented by the Badische Anilin und Soda Fabrik (this Journal, 1890, 497 and 609). Those examined are—(1) trihydroxybenzophenone prepared from benzoic acid and pyrogallol, and known as alizarin yellow; (2), tetrahydroxybenzophenone, from salicylic acid and pyrogallol; and (3) tetrahydroxyphenyl-naphthylketone from gallic acid and naphthol (Alizarin W). From the first of these a mono- and a dimethyl-derivative have been obtained, but the third hydroxylic hydrogen atom could not be displaced by methyl or ethyl. The acetyl-derivative—

has, however, been obtained, and confirms the presence of three hydroxyl-groups. Heated with concentrated sulphuric acid at 100°, or with slightly diluted acid at 130—140°, trihydroxybenzophenone is decomposed, yielding benzoic acid and pyrogallolsulphonic acid. Tetrahydroxybenzophenone suffers decomposition in the same way. In the latter compound the relative position of the CO group in the pyrogallol nucleus is shown in the formula—

This is proved to be the case by the fact that when tetrahydroxybenzophenone is heated with water at 180—220° water is split off and dihydroxyxanthone—

is formed.—A. K. M.

Action of Dihydroxyquinone on Orthodiamines. R. Nietzki and G. Hasterlik. Ber. **24**, 1337—1340.

NIETZKI and Kehrman (Ber. **20**, 3150) showed that tetrahydroxyquinone reacts with orthodiamines like an orthodiketone, but the question as to whether the product was a phenazine derivative, or whether it contained a quinone-imido group, was not settled. The authors now find that dihydroxyquinone reacts with orthophenylenediamine, yielding dihydroxyphenazine, and similarly with other orthodiamines. With orthotoluylenediamine it gives an azine of the formula $\text{C}_{15}\text{H}_{19}\text{N}_3\text{O}_2 + 2\text{H}_2\text{O}$, melting at 265° and crystallising from dilute alcohol in red needles, and from strong alcohol in yellowish-brown plates. The azine obtained from 1:2 naphthylenediamine crystallises in reddish-brown needles melting at about 300°.

The authors are still unable to decide the question of the constitution of these substances (compare Kehrman, this Journal, 1890, 331).—A. K. M.

Alizarin sulphonic Acids and the Conversion of Anthraquinone α - and β -Disulphonic Acids into Flavopurpurin and Anthrapurpurin. R. E. Schmidt. J. Prakt. Chem. **43**, 232—237.

AN examination of the intermediate products obtained on fusion of anthraquinone- α - and β -disulphonic acids with caustic soda for conversion into flavopurpurin and anthrapurpurin respectively has shown that they are isomeric alizarin monosulphonic acids of the formula—

Their general character, and especially their conversion into alizarin-blue sulphonic acids, were greatly in accord with this view, which is now confirmed by the formation of these acids from alizarin. When alizarin is treated with fuming sulphuric acid a mixture of two disulphonic acids is obtained, and on heating these with sulphuric acid of 60° B. at 180°, hydrolysis of one of the sulpho-groups occurs, and a mixture of two isomeric alizarin monosulphonic acids is produced; these are identical with the products mentioned above. When the mixed acids are fused with potash, flavopurpurin and anthrapurpurin are obtained in about equal quantities.

—A. K. M.

New Colouring Matters of the Anthraquinone Series.

R. E. Schmidt. J. Prakt. Chem. **43**, 237—246.

WHEN alizarin is heated at 130—140° with an excess of fuming sulphuric acid containing 70 per cent. of anhydride, and the product subsequently hydrolysed, a colouring matter is obtained which is different from alizarin. The same product is formed without sulphonation taking place when alizarin is treated at a temperature of 25—30° with a large excess of sulphuric anhydride (75—85 per cent. fuming acid). On pouring the product on to ice an insoluble orange-yellow intermediate substance is obtained; this appears to be the sulphate of *Alizarin-bordeaux*, for when it is dissolved in alkali, the solution acidulated and boiled, the new dye is precipitated. Other Bordeaux have been prepared from purpurin, anthragallol, flavopurpurin, and anthrapurpurin.

With alumina mordants Alizarin-bordeaux gives Bordeaux shades, and a black-blue with chrome mordants; it will dye wool an intense blue similar in shade to Alizarin-blue. The colours are extremely fast. It is characteristic of all the "Bordeaux" that they give solutions with concentrated sulphuric acid, which are considerably bluer than those obtained from the mother-substances.

Other anthraquinones, namely, quinizarin, xanthopurpurin, anthranthin, hydroxyflavopurpurin, hydroxyanthrapurpurin, and rutigallie acid, have also been treated with sulphuric anhydride and converted into dyes of the same class. Alizarin-bordeaux has been submitted to a second treatment with sulphuric anhydride and converted into another new product. Full details of the methods employed and descriptions of the products are given in the German patents.

Alizarin-bordeaux yields a mononitro-derivative which is the analogue of Alizarin-orange, and with mordants yields shades similar to those given by flavopurpurin. The amido-derivative behaves like β -amidoalizarin. Alizarin-bordeaux also yields a blue corresponding to Alizarin-blue, but identical with the *Alizarin indigo blue* of the Badische Anilin und Soda Fabrik. When Alizarin-bordeaux is treated with sulphuric acid and manganese dioxide or arsenic acid, it does not yield a Purpurin-bordeaux, as was expected, but is converted into a new and valuable colouring matter, "*Alizarin-cyanine R*," which dyes an intense blue with chrome-mordants and a violet with alum-mordants; wool is dyed greenish-blue. The same product is obtained on the oxidation of Purpurin-bordeaux, whilst the Bordeaux from flavopurpurin and anthrapurpurin give other but similar *Cyanines*. Alizarin-bordeaux can be oxidised to another dye by sulphuric acid alone, the product in some respects resembling alizarin-cyanine.

Colouring-matters are also obtained by the action of sulphuric anhydride on anthraquinone, dibromanthracene and dichloranthracene.

When Alizarin-bordeaux sulphate mentioned above is treated with ammonia and the solution acidulated a dye is obtained bluer in shade than Alizarin-bordeaux.

If the oxidation of Alizarin-bordeaux be conducted at not too high a temperature, the product poured into ice water and the precipitate filtered off in the cold, an intermediate product is obtained which is readily converted into Alizarin-cyanine R, by boiling with water or dilute acids. By the action of ammonia on this intermediate product another important colouring matter, *Alizarin-cyanine G*, is obtained which gives considerably bluer shades than Alizarin-cyanine R. Similar dyes can be obtained also from the intermediate products which are formed during the preparation of the *Cyanines* from Flavopurpurin-bordeaux and Anthrapurpurin-bordeaux.—A. K. M.

Naphthol-Sulphonic Acids and Naphthol-Sultones. R. Nietzki. Chem. Zeit. 15, 296—297.

THE author has examined a compound which is produced along with β -naphthol-trisulphonic acid in the manufacture of the latter, and which possesses the characteristic properties of a sultone (this Journal, 1890, 491 and 1421). β -Naphthol-trisulphonic acid is prepared by mixing 1 part of β -naphthol with 5½ parts of anhydro-sulphuric acid containing 40 per cent. of anhydride, at a temperature not exceeding 90°, and then heating to 120° for six hours. After cooling, the mass is poured on to 3 parts of ice. The compound in question separates from the cold solution in the form of a sandy, crystalline powder, which is filtered-off and pressed. For the purpose of investigation, the cakes so obtained were mixed with water, almost neutralised with soda, and the sodium salt of the sultone derivative isolated by repeated precipitation with common salt from a hot solution, until the yellow-green fluorescence of sodium β -naphthol-trisulphonate no longer appeared on the addition of alkali to the mother-liquor. The sodium salt of β -naphthol-sultone-disulphonic acid differs from that of β -naphthol-trisulphonic acid in the following respects:—

1. Its solution is yellow, but without fluorescence.
2. Diazo-naphthalene-sulphonic acid and other diazo-compounds do not combine with it.
3. It is not coloured violet by ferric chloride.

It is converted into the trisulphonic acid by boiling for a short time with caustic soda.

Analyses of the sodium salt gave numbers corresponding with the formula—

As the constitutional formula of β -naphthol-trisulphonic acid is—

those of the isomeric β -naphthol-disulphonic acids, from both of which it is obtained by further sulphonation, being respectively—

the formula of the sultone must be—

The author has not as yet succeeded in preparing this ortho-sultone by the diazo reaction from the corresponding β -naphthylamine-trisulphonic acid, but has had to suspend his experiments through lack of material. He is pursuing the subject further.—E. B.

PATENTS.

Improvements in the Manufacture of Colouring Matters. W. R. Lake, London. From A. Leonhardt & Co., Mühlheim-on-the-Maine, Germany. Eng. Pat. 8243, May 27, 1890. 6d.

THESE products are derivatives of the acridine series and are orange dyestuffs, having the general formula—

They are produced from tetramido compounds of the formula—

by the elimination of ammonia and subsequent oxidation. The compounds are obtained by condensing aldehydes such as formaldehyde or benzaldehyde with aromatic substituted *m*-diamines such as *m*-amidodimethylaniline, or, the aldehydes may be condensed with tertiary aromatic amines, such as dimethylaniline, two other amido groups being subsequently introduced by nitration and reduction. Ammonia is eliminated by heating the tetramido bodies with a mineral acid, and the oxidation is carried out preferably by the use of ferric chloride. Instead of first forming the leuco compounds from formaldehyde the colouring matters can be obtained directly by heating a mixture of formic acid or oxalic acid and glycerol with aromatic diamines in presence of a condensing agent. The dyestuffs obtained by the use of this invention dye mordanted cotton orange, silk dyed with the colouring matter shows a brilliant green fluorescence.—T. A. L.

The Manufacture of New Derivatives of Alizarin and its Analogues. B. Willcox, London. From the "Farben-fabriken vormals F. Bayer & Co.," Elberfeld, Germany. Eng. Pat. 8725, June 5, 1890. 6d.

A DISULPHONIC acid of alizarin is produced when 20 kilos. of dry powdered alizarin or its mono-sulphonic acid or salts, and 253 kilos. of fuming sulphuric acid containing 24 per cent. of anhydride are heated from 135°—140° C. for about six hours. Samples are taken out from time to time, poured into water, boiled and made strongly alkaline with caustic soda. The sulphonation is complete when the blue colour of this solution does not increase in depth. The melt is then poured into 1,000 litres of water, boiled, and after cooling the disulphonic acid is separated by the addition of potassium chloride. By heating 10 kilos. of this acid with 60 kilos. of sulphuric acid of 60 B. at 180°—190° C. for about six hours, one sulphonic acid group is split off and

an alizarin mono-sulphonic acid is obtained identical with that described in Ger. Pat. 50,161. Another derivative of alizarin described in the present patent is a product insoluble in water which has been termed "Alizarin-bordeaux." This is produced by the action of a large excess of sulphuric acid anhydride on alizarin at a temperature not exceeding 60° C. 10 kilos. of dry ground alizarin are stirred into 100 kilos. of 70 per cent. anhydride at a low temperature and kept at 35–40° C. for 24–48 hours until a sample poured on to ice and saturated immediately with caustic soda lye gives a yellowish-red solution, when the melt is poured into 200 kilos. of sulphuric acid of 60 B., and this mixture poured into 2,000 litres of water, the whole boiled, filtered, and the precipitate dissolved by boiling with caustic soda in 2,000 litres of water. The boiling solution is then decomposed with hydrochloric acid which precipitates the alizarin-bordeaux. After filtering and washing it may be employed in the form of a paste. Alizarin-bordeaux crystallises from glacial acetic acid or nitrobenzene. Its solution in concentrated sulphuric acid is a bright bluish-violet, and the shades obtained with mordants are much bluer than those from alizarin. It can also be nitrated in an acetic acid solution yielding nitro-alizarin-bordeaux, and this on reduction forms amido-alizarin-bordeaux which can be converted into a quinoline derivative by means of Skrap's synthesis. The product thus obtained differs from alizarin blue (which dissolves in sulphuric acid with a reddish-brown colour) by the blue colour of its solution in sulphuric acid. Similar bodies to the Alizarin-bordeaux may also be obtained from purpurin, flavopurpurin, anthrapurpurin and anthragallol.—T. A. L.

Manufacture of Phenol Ether and Oxydiphenyl, their Homologues and Analogues. J. Dawson and R. Hirsch, Huddersfield. Eng. Pat. 9080, June 12, 1890. 6d.

WITH aqueous solutions of diazobenzene, diazotoluene, diazonaphthalene, or of other aromatic diazo-compounds are mixed with phenol the diazo salt appears to dissolve in the phenol, forming a compound $C_6H_5 \cdot N \equiv N \cdot O \cdot C_6H_5$. The solution is tolerably stable at low temperatures, but on heating gives off nitrogen and forms phenol ether, $C_6H_5 \cdot O \cdot C_6H_5$, *o*- and *p*-hydroxydiphenyl, and small quantities of the mixed ether $C_6H_5 \cdot O \cdot C_6H_4 \cdot C_6H_5$. The following method is employed in working the process.—10 kilos. of aniline, 10 litres of water, and 30 kilos. of hydrochloric acid are diazotised with 7.5 kilos. of sodium nitrite in 15 litres of water. The solution thus obtained is shaken with 30 kilos. of phenol, which is then drawn off, and the treatment repeated three times with 10 kilos. of phenol. The solutions, after mixing, are decomposed by heating in a vessel provided with a condenser. The water formed in the reaction is drawn off, the phenol solution distilled, and the distillate collected, that which comes over at 200–350 weighing about 14 kilos. This is mixed with 30 kilos. of toluene, and the warm toluene solution shaken with a 5 per cent caustic soda solution until nothing more is extracted. The toluene solution is then distilled, and the phenol ether collected which comes over at 243–290 weighing 2.5 kilos. After rectification it boils at 255–258. The caustic soda solution is precipitated with hydrochloric acid and yields about 12 kilos. of *o*- and *p*-hydroxydiphenyl, which may be separated by crystallisation from glacial acetic acid or by fractional distillation. Several ethers and hydroxy derivatives have been obtained by this method, and the melting and boiling points of some of them are given in the specification.—T. A. L.

Improvements in the Production of Naphtholtrisulphonic Acid, Naphtholtrisulphonic Monomide, Dicarboxynaphthalene-disulphonic Acid, and the Colouring Matters derived therefrom. O. Imray, London. From H. Koch, Marburg, Germany. Eng. Pat. 9258, June 14, 1890. 8d.

SODIUM naphthalene trisulphonate is dissolved in four times its weight of sulphuric acid, the requisite amount of concentrated nitric acid added to form a mononitro derivative, and the reaction completed on the water-bath. The

melt is then diluted with water, reduced with iron, limed, filtered, and converted into the sodium salt. A new naphthylaminetrisulphonic acid is thus produced which differs from the two known isomers by forming a colourless diazo compound, and by being non-fluorescent in an alkaline solution. On boiling the aqueous diazo solution of this acid it is converted into a naphtholtrisulphonic acid. If a concentrated solution of the sodium salt of this acid be made acid and allowed to stand, it deposits needles of the sodium salt of naphtholsulphone-disulphonic acid—

which on treatment with ammonia yields the sulphamide $C_{10}H_7(OH)(SO_2NH_2)(SO_3Na)_2$. On fusing with caustic soda, the naphtholtrisulphonic acid or its anhydride (the naphtholsulphone-disulphonic acid) form dihydroxynaphthalene-disulphonic acid. All these hydroxynaphthalene compounds are capable of combining with diazo compounds to form colouring matters, and can be employed in the well-known manner.—T. A. L.

Improvements in the Production of Blue-Green Colouring Matters of the Malachite Green Series. O. Imray, London. From the "Farbwerke vormals Meister, Lucius, and Brünig," Höchst-on-the-Maine, Germany. Eng. Pat. 9530, June 19, 1890. 6d.

AN extension of Eng. Pat. 12,796 of 1888 (this Journal, 1889, 701) and of Eng. Pat. 14,822 of 1888 (this Journal, 1889, 980). It has been found that the sulphonic acids of the *m*-chloro-tetraalkyl-diamido-triphenyl carbinols are also fast blue-green acid colouring matters. The *m*-chloro-tetraalkyl diamido-triphenyl methanes are obtained from the *m*-diazo-tetraalkyl diamido-triphenyl methanes by decomposing them with molecular copper in presence of hydrochloric acid, according to Gatterman's method (Ber. 23, 1218; this Journal, 1890, 823). The subsequent treatment of the products so obtained is similar to that employed for the production of colouring matters from the corresponding hydroxy derivatives.—T. A. L.

Improvements in and relating to the Manufacture of Substantive Dyestuffs and of New Materials therefor. J. Y. Johnson, London. From the "Badische Anilin und Soda Fabrik," Ludwigshafen, Germany. Eng. Pat. 9537, June 19, 1890. 6d.

A NEW α -naphthol-monosulphonic acid can be obtained from β -naphthylamine disulphonic acid G, in two ways. Either the amido-group is first removed by means of the hydrazine method and the (1'3) naphthalene disulphonic acid thus obtained fused with caustic soda so as to replace one SO_3H group by OH, or β -naphthylamine disulphonic acid G, $(NH_2 \cdot SO_3H : SO_3H \quad 2:1':3')$ on fusion with caustic soda yields amidonaphthol sulphonic acid G.—

(Eng. Pat. 15,176 of 1889; this Journal, 1890, 855), and on removing the NH_2 group gives the same α -naphthol-sulphonic acid as above. A valuable blue colouring matter is obtained from this product by combining it with the diazo-compound from *o*-diamidine, the shade obtained being superior to that given by Benzazurine.—T. A. L.

Improvements in and relating to the Manufacture of Substantive Dyestuffs, and of Materials therefor. J. Y. Johnson, London. From the "Badische Anilin und Soda Fabrik," Ludwigshafen, Germany. Eng. Pat. 9676, June 21, 1890. 6d.

THIS specification describes the preparation of derivatives obtained from (1'1') naphthylamine sulphonic acid which yields the following products:—1. On fusion with caustic soda it gives a new (1'1') amido-naphthol. 2. This amido-

naphthol can be sulphonated and combines then with tetrazo-compounds yielding dull substantive colouring matters. 3. Bright dyestuffs are produced by replacing hydrogen in the amido-group by an acid radicle of the fatty or aromatic series such as acetyl or benzoyl previous to combination with the tetrazo-compounds. These substances dye unmordanted cotton from a bath containing caustic alkali. 4. By choosing combinations such that the total number of sulphonic or carboxylic acid groups is increased in the finished dyestuff, more soluble colouring matters are obtained which dye unmordanted cotton from a neutral, alkaline, or soap bath. A colouring matter of this class is obtained by diazotising diamidodiphenyldicarboxylic acid ($\text{NH}_2:\text{CO}_2\text{H} = 1:2$) and combining it with (1.1') benzoylamidonaphtholsulphonic acid. The colouring matter is soluble in hot water and can be precipitated by adding salt.—T. A. L.

A Process for the Production of a New α -Naphthylendiamine-mono-sulpho Acid. J. Dawson and R. Hirsch, Huddersfield. Eng. Pat. 9768, June 24, 1890. 6d.

By slowly adding β -naphthylamine nitrate to sulphuric acid monohydrate and afterwards adding fuming sulphuric acid containing 20 per cent. of SO_3 , a mixture of two naphthylamines is obtained which melt respectively at 143° and 105° , the acetyl compounds of both melting at 197° . The nitronaphthylamine of melting point 143° yields a naphthylene-diamine on reduction which is oily, but gives an acetyl-compound of melting point 260° . The naphthylene-diamine on sulphonation with fuming sulphuric acid gives a monosulphonic acid almost insoluble in cold water, crystallising in small needles which contain water, and on boiling with an insufficient quantity of water change into short heavy prisms.—T. A. L.

Improvements in the Manufacture of Trihydroxybenzophenone, a Colouring Matter of the Oryketone Group. J. Y. Johnson, London. From the "Badische Anilin und Soda Fabrik," Ludwigshafen, Germany. Eng. Pat. 10,095, June 30, 1890. 4d.

As extension of Eng. Pat. 8373 of 1889, and of Eng. Pat. 9428 of 1889 (this Journal, 1890, 497), describing a new process for the production of trihydroxybenzophenone consisting in boiling together pyrogallol in alcohol containing 10 per cent. of water and adding benzotrichloride slowly. After the reaction is complete the whole is poured into a large quantity of boiling water and filtered, when the trihydroxybenzophenone crystallises out on cooling and may be filter-pressed, washed, and dried, or preferably used as a paste.—T. A. L.

Improvements relating to the Manufacture of Colouring Matters. H. H. Lake, London. From K. Oehler, Offenbach-on-the-Maine, Germany. Eng. Pat. 10,599, July 8, 1890. 6d.

These colouring matters belong to the hydrazone series, and are produced by combining nitro-xylylhydrazine sulphonic acid with dihydroxytartaric acid. The nitroxylylhydrazine sulphonic acid may be produced from diazotised nitroxylylene sulphonic acid by sodium bisulphite or by means of stannous chloride. The condensation with the dihydroxytartaric acid takes place slowly and is completed by heating the mixture to 80°C , when the dyestuff forms a yellow crystalline powder which dyes a greenish yellow and is said to be faster to milling than tartrazine.—T. A. L.

Manufacture of Colouring Matters derived from Pyrogallollic Acid, and their Application to Dyeing and Printing. J. C. L. Durand, D. E. Huguenin, and A. J. J. d'Andiran-Koechlin ("La Société L. Durand, Huguenin et Cie.") Bâle, Switzerland. Eng. Pat. 3263, February 23, 1891. 4d.

YELLOW to brown colouring matters are produced by combining the diazo-compounds from aniline, *p*- and *m*-nitraniline amido-azobenzene and its monosulphonic acid or the tetrazo-compounds from thio-aniline and thio-*p*-toluidine with pyrogallol. The colouring matters will dye unmordanted wool and silk from an acid bath, but are principally to be used in conjunction with a mordant when very deep shades can be obtained and the goods will stand the most severe fulling.—T. A. L.

PATENTS.

Improvements in the Manufacture of Artificial Horsehair from Vegetable Fibre. H. H. Lake, London. From K. Müller, J. Schwarz, and M. Scheid, Freiburg, Germany. Eng. Pat. 3725, March 8, 1890. 4d.

THE incrusting substances of Mexican grass or similar fibres may be dissolved by boiling for about two hours in an alkaline liquor of 1 or 2 per cent. strength with or without pressure according to the thickness of the fibres. These are then washed and placed for 15 to 20 minutes either in a mixture of 2 to 3 parts of sulphuric acid and 1 part of water, or in a solution of zinc chloride. The fibres are hereby parchmentised, and after being washed and combed they assume a hair-like character, and possess greater elasticity than real horsehair.—H. S.

Improved Processes for the Nitration and Denitration of Cellulose and for Regaining the Acids Employed and Apparatus Employed in Connection therewith. H. de Chardonnet, Paris, France. Eng. Pat. 5376, April 8, 1890. 8d.

See under XIX., page 566.

Improvements in the Retting and Scouring of Textile and other Fibres. C. Vicomte de la Roche, Paris, France. Eng. Pat. 8180, May 24, 1890. 6d.

THE patentee has found that the pectic, resinous, or gummy substances of vegetable textile fibres, such as flax, hemp, china-grass, jute, and the like, as well as of peat, &c. may be dissolved by fatty acids. To effect this, the raw fibres are boiled for about three or four hours in soapy water, until thoroughly impregnated with it. Then ammonium chloride solution is added (1 part NH_4Cl to 3 parts of soap) which decomposes the liquid and sets free the neutral insoluble fatty acids. These dissolve the resinous substances of the fibres, so that after two or three hours treatment the fibres are freed from all gums or resins, but impregnated with fatty acids. These are then saponified by a further treatment for about two hours with a slightly caustic lye. After this, the fibres are washed and dried, and then found to be disintegrated. China-grass and other foreign fibres which contain more refractory pectic matter

must be treated with borated water after the fibres have been washed as above described. The fibres produced by this process are said to be uniform and stronger than the best fibres obtained by the ordinary retting process. When the material is to be used for paper pulp, the process may be assisted by a kneading or agitating apparatus to facilitate the removal of the gummy matters.—H. S.

Improvements in Machines for Preparing Flax, Hemp, Jute, Wool, and other Fibres. A. T. Lawson, F. W. Lawson, and S. Dear, Leeds. Eng. Pat. 8475, May 31, 1890. 8d.

This patent deals with machines in which chains are used to carry the rollers or gill bars. The links in which the gill bars are held, are in this invention made with U-like openings at the top, into which the necks of the gill bars are introduced. It is possible by this arrangement to take out any bar at the top of the chain. To keep the bars in their places, guides are put around the chain, covering the necks of the bars. Sometimes the guides may be dispensed with, by providing the links with loose caps, screwed on the top. These caps can be removed, and any bar taken out.—H. S.

Improvements in Machines for Decorticating Ramie and other Textile Plants in a Dry or a Green State. P. A. Favier, Paris, France. Eng. Pat. 8520, June 2, 1890. 8d.

The object of this invention is to obtain ramie and other textile fibres freed from all ligneous parts which are removed immediately after the crushing, bruising, and breaking operations. The machine consists of a series of horizontal rollers and scrapers arranged in pairs (one roller or scraper above the other), between which the stalks of the material are crushed, broken, and the woody parts disengaged and separated from the fibres.

At the front end of the machine is a table for the distribution and division of the stalks, and at the other end of it is an endless cloth intended to receive the fibres as they issue from the machine. Between the rollers—the majority of which are fluted—and the scrapers, large spaces are left in which the stalks are submitted to the action of beaters, which facilitate the fall of the ligneous parts as well as the passage of the strips of material. Other spaces are left between the lower row of friction rollers at the end of the machine, permitting the pellicles and the few splinters, which might have passed notwithstanding the action of the beaters, to fall more easily from the textile material to which they adhered. The scrapers work at great speed, and in the same pair of scrapers their blades or projections pass between each other without touching or meeting, and the end of each blade in travelling approaches the circular bottom of the corresponding scraper, leaving exactly the space necessary for the scraping of the material which is thus scraped without injury to the fibres. The rollers and beaters at the front end of the machine may be in two parts, separated by a middle partition, whilst further down they extend the entire breadth of the machine.—H. S.

A Method or Process of Treating Silk or Mixed Silk Fabrics to give them the Appearance of China Crape. D. Gantillon, Lyons, France. Eng. Pat. 14,246, September 10, 1890. 4d.

The fabric, in the state in which it comes from the dyer or weaver, is wound on a steaming column without stretching it lengthwise or breadthwise, an intermediate cotton or linen cloth being employed, to which sufficient tension is given while winding it on the column. Then the fabric is submitted to the steaming operation from 5 to 15 minutes under a pressure of 4 or 5 atmospheres, and after that it is unwound and folded ready for market. The effects produced can be varied according to the texture of the intermediate cloth.—H. S.

Improved Means for Imparting a Silky Appearance to Fabrics, Threads, and Fibres. C. Brodbeck, Paris, France. Eng. Pat. 18,119, November 11, 1890. 6d.

This invention consists in applying a solution of fibroine of silk to fabrics, threads, or fibres which have been scoured, lixiviated, and bleached, and the tissues calendered by friction and beetled. They are then hydrated and physically modified by passing them through a solution of caustic potash or soda of 1.35—1.40 sp. gr., or of sulphuric acid of 1.53—1.56 sp. gr. In both cases a low temperature of 4—8 C. is required. If animal fibres are present, no caustic alkalis can be used. Cellulose is by this treatment freed from most of the impurities which it contains when imperfectly bleached, which renders the fixing of the silk easier and more perfect. After careful washing and drying the fabrics or fibres are treated with concentrated solutions of silk, the fibroine being dissolved either in hydrochloric, phosphoric, or sulphuric acid, or in pure cuprammonium, &c. If the solution of silk is effected in more or less hydrated sulphuric acid, the temperature must be about 0 C. to avoid decomposition. Silk in any form may be dissolved; hence scraps, cocoon silk, waste silk, and other material which was hitherto practically useless may thus be utilised. Previous to silkifying cellulose fabrics they should be subjected to the action of a metallic or tannic mordant, the selection of which depends on the colour which the fabric is to receive. This is of advantage in combining the silk more intimately with the cellulose. The impregnation with the silk solution is effected by passing the material through a tightly-closed impregnating apparatus with only two openings, one for the inlet and the other for the outlet of the material. It then passes through a hot-air drying apparatus, and subsequently through a second vessel containing liquids with which the solvents employed combine, the silk being hereby precipitated upon and fixed in the pores of the fibres. The material is then washed and dried. Should it be desired to increase the amount of silk, the silkifying process may be repeated as often as desirable. Materials rendered silky in this way may be bleached by the same means as those employed for real silk. All fabrics which have been treated by this process must be subjected to a mechanical finishing, beetling, calendering, rubbing, brushing, polishing, and pressing according to the purpose for which they are destined, in order to impart to them a glossy appearance and silky feel.—H. S.

Improvements in Machines for Cleaning Vegetable Fibre. W. C. McBride, Brooklyn, U.S.A. Eng. Pat. 20,353, December 13, 1890. 8d.

From fibrous vegetable substances which have been subjected to a crushing process, extraneous matters may be removed by a machine which consists of two shafts revolving in opposite directions, and bearing scrapers which are so arranged that they interlock or overlap each other in a slight degree. Below the scrapers are two tension rollers, between which the fibres may be gripped, revolving in the same directions as the shafts above them. The top of the machine is covered, except in the middle part of it above the scrapers, where an opening is left, and provided with two rack-bars forming rails on which two holders travel (one on each side of the machine), which are used alternately to convey the fibrous stock to the scrapers. In the middle of these holders is a fluted roller which can be made to revolve by means of a crank. Each holder is provided with a jaw which may be opened by raising it. This jaw has two elastic rollers, which are so arranged as to rest saddlewise on the fluted roller. On both sides of the fluted roller the jaw has a number of dabbing brushes, which are of sufficient length to reach nearly to the cover of the machine. The jaw, when closed, is held down firmly to the holder by means of springs and a rope. The material to be treated is placed in the holder across the fluted roller, and the jaw shut down. The elastic rollers and the brushes bear upon the fibres, the whole mass of which is subjected to the action of the scrapers by causing the holder to travel backwards and forwards, and by a proper manipulation of the fluted roller as well as of the tension rollers, hereby cleaning the fibres.—H. S.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

An Improved Oil-Bath for Dyeing Laboratories.
R. L. Whiteley.

See pages 521—522.

Fastness of Aniline Black Dyes. W. Evans. Chem. Zeit. 15, 43 and 75.

The author states that certain methods of dyeing with aniline black by means of the dry oxidation process will give fast dyes provided that the oxidation can be properly effected. Koechlin gives the following recipe:—

- 10 parts of potassium chlorate.
- 10 parts of ammonium chloride.
- 10 parts of copper chloride.
- 20 parts of aniline oil.
- 20 parts of hydrochloric acid.
- 200—300 parts of water.

Cotton and silk fabrics impregnated with this solution have to be suspended for 24 hours in oxidation chambers at a low temperature and then washed. No potassium bichromate is used. The chief difficulty of this method is to effect the solution of the different substances in 200 or 300 parts of water, as above described. If 300 parts of water are used, a deep black cannot be obtained; but in using 200 parts it frequently happens that aniline black is formed in the impregnating liquid, in which case the dye will never be fast, as a mechanical precipitation of dye particles upon the fibres is unavoidable. But if this forming of aniline black in the liquid can be prevented, the dye obtained by the subsequent oxidation will be found to be perfectly fast. To effect this the liquid should be mixed and kept at low temperatures, should not contain much acid and should be filtered before being used a second time as afterwards described. The following modification of Koechlin's recipe has been found by the author to give very good results:—

- 10 parts of sodium chlorate.
- 10 parts of ammonium chloride.
- 10 parts of copper sulphate.
- 35 parts of aniline salt.
- x parts of aniline oil.
- 200 parts of water.

Copper sulphate and sodium chlorate are substituted on account of their much greater solubility in water, 55 parts of water being necessary for 10 parts of copper sulphate, and 65 parts of water for 10 parts of sodium chlorate and 10 parts of ammonium chloride together; the 35 parts of aniline salt required have to be dissolved in a small quantity of hot water, and then neutralised by aniline oil. All these substances are dissolved separately and have to be carefully mixed when perfectly cold, by first adding the aniline salt solution to the sodium chlorate and ammonium chloride, and then adding the copper sulphate solution. The mixture is diluted with water to 9.5° B. This solution has always to be kept at a low temperature, especially in hot weather. The fabrics to be dyed have to be cleaned and dried before being impregnated with the liquid, which must be renewed after having been used for 10 pieces of material. When properly filtered the liquid may be re-used for the necessary dilution of fresh mixture. A fast dye can be obtained by other methods as well, if the forming of aniline black in the liquid can be avoided. To add starch, dextrin, &c. as has been recommended, is useless. In ordinary oxidation chambers, very good results were obtained with a temperature of 30° C. and 25° moisture, the oxidation being completed within 14 hours. The black was developed by treating the fabrics at 80° C. with a solution containing 1 per cent. of potassium bichromate, 0.5 per cent. of soda, and 0.5 per cent. of sodium chloride. If by accident some unfast pieces are obtained, it is impossible to improve the colour, except by repeating the dyeing, which, however, is not to the advantage of the fabrics. The author did not obtain satisfactory results with Prudhomme's or with the vanadium and cerium method.

—H. S.

PATENTS.

An Improved Process of Bleaching Textile Fibres. W. Hitchcock-Spencer, Hitchin. Eng. Pat. 7198, May 8, 1890. 6d.

The improvement relates to the bleaching of textile fibres, whether vegetable or animal, and particularly reed-grass, without steeping. It consists in treating the slightly moistened fibre, contained in a suitable chamber, with chlorine gas.—W. E. K.

Improvements in Black Dyeing "Piece Goods" or Fabrics. A. North, Bradford. Eng. Pat. 8799, June 7, 1890. 4d.

This improvement consists in "topping" with Methylene blue after the cloth has been dyed black by well-known methods.—W. E. K.

An Improved Ink. T. W. Just, R. Weiler, and O. Heidepriem, Melbourne, Australia. Eng. Pat. 16,757, October 21, 1890.

This invention is for an ink which is permanent and unaffected by the application of acids, alkalis, &c., and which renders forgeries and erasures, additions, or alterations easy of detection and difficult to accomplish. To carbon black (preferably prepared by the action of concentrated sulphuric or other acid on sugar) are added a solution of gum arabic or other mucilage, caustic soda, oxalic acid, and Indian ink. Vanadium in any form, Aleppo galls, nut galls and a small quantity of an aniline dye are then added along with sufficient water to make the ink flow readily. The following proportions yield good results:—Nut galls, 20 per cent.; Aleppo galls, 5 per cent.; carbon black, 10 per cent.; "vanadium, 1 per cent."; Indian ink, 10 per cent.; oxalic acid, 3 per cent.; aniline dye, 1 per cent.; rain water, 50 per cent. "The whole is boiled, filtered, and strained."—B. H.

VII.—ACIDS, ALKALIS, AND SALTS.

Recent Determinations of the Specific Gravities of Hydrochloric Acids of different Strengths. G. Lunge and L. Marchlewski. Zeits. f. angew. Chem. 1891, 133—135.

REASONS similar to those which caused Lunge and Isler (this Journal, 1890, 501) to redetermine the specific gravities of sulphuric acids, prompted also the extension of this work to hydrochloric acid and nitric acid. The analytical method used was similar to that followed in the sulphuric acid determinations. The acid was weighed in a Winkler pipette, and stronger acids in glass bulbs. The pyknometer was provided with a ground-in thermometer, previously compared with two normal thermometers and corrected accordingly. The water value of the apparatus had been repeatedly determined at the beginning, middle and end of each experimental series. All determinations were made at 13°, 15°, and 17° C. and at least once repeated, and with a different pyknometer. The authors are thus enabled to guarantee the specific gravities to ± 0.0001 . The specific gravities were reduced to 4°, and vacuo by means of Kohlrausch's formula.

The acids were analysed with a caustic soda solution, which was titrated with a one-fifth normal hydrochloric acid, and this was standardised with sodium carbonate and checked gravimetrically with silver nitrate. The same acid, independently made and agreeing to about 0.02 per cent. with the previous one, served also for Lunge and Rey's determinations of the specific gravities of nitric acids (see following abstract).

The diagram constructed from the specific gravities and the corresponding percentages represents an almost perfectly straight line, which for weaker acids agrees fairly well with the one obtained by Kolb. The observations taken between 13° — 17° should be reduced to 15° by deducting the following figures for every degree for readings below 15° and adding them above 15° .

Specific gravity	1.000—1.040 :	± 0.0002
	1.041—1.085 :	0.0003
	1.086—1.120 :	0.0004
	1.121—1.155 :	0.0005
	1.156—1.200 :	0.0006

For Table see page 542.

—H. A.

Specific Gravities of Nitric Acids of different Strengths.

G. Lunge and H. Rey. Zeits. f. angew. Chem. 1891, 165—170.

For these determinations a pipette of a special form has been used, which prevents any loss of acid vapours in pipetting, weighing, and delivering the requisite quantities of acid.

The low-strength nitric acids were obtained in a pure form by blowing a current of air or carbonic acid through the warm acids. The preparation of the pure high-strength acid succeeded best by adding to the pure 98.7 per cent. acid double its volume of monohydrated sulphuric acid and distilling the mixture in vacuo. The temperature in the retort rose only to 35° and the colourless distillate contained 99.7 per cent. of HNO_3 .

The results differ from those obtained by Kolb only for the highly-concentrated acids. In this case Kolb's figures are on a straight line, whilst Lunge and Rey's figures diverge.

The following correction should be applied for observations taken between 13° — 17° C.

Specific Gravity.	Correction for $\pm 1^{\circ}$ C.

PATENTS.

Improvements in the Manufacture of Soda and Potash. F. Ellershausen, Hebburn-on-Tyne. Eng. Pat. 1015, January 20, 1890, 6d.

A sodium sulphide solution of say 40° Tw. is passed through a filter bed of granulated sodium ferrate (Eng. Pat. 9112 of 1890, see page 547), obtained by roasting sodium

carbonate with iron peroxide. Caustic soda is formed and an insoluble double compound of sodium and iron sulphide is left behind. The reaction takes place in two stages: first of all the water of the sodium sulphide solution decomposes the sodium ferrate with formation of caustic soda and iron hydroxide, which latter, on acting upon sodium sulphide, will yield more sodium hydrate and the insoluble sodium-iron sulphide. The degree of concentration of the resulting solution is increased by reason of the fact that sodium ferrate, in its conversion into caustic soda, absorbs water from the solution.

The soda contained in the sodium-iron sulphide is utilised for the production of sodium sulphate, sulphite, or hyposulphite, according to a subsequent patent (Eng. Pat. 16,676 of 1890, not yet published).—H. A.

Improvements in the Means or Apparatus to be Employed in the Production of Solutions containing Sulphurous Acid or its Salts. G. Horsley, West Hartlepool, and A. C. Wilson, Stockton-on-Tees. Eng. Pat. 3992, March 14, 1890, 8d.

The apparatus consists of a tower lined with acid-resisting material, and provided with perforated shelves and corresponding apertures for charging and stocking up the basic material, such as lime or magnesia when sulphites are to be produced. In the case of limestone or dolomite the bottom part only of the tower need be provided with shelves. The sulphurous acid is injected by means of a steam jet in an admission chamber in the bottom part of the tower. In its upward course the gas is absorbed by the charge, and the condensation may be completed by means of a spray of cold water or lime solution, which is introduced in the top part of the tower. At the base of the tower is a tank for catching and delivering the sulphite solution which drains down. For the production of a solution of sulphurous acid the shelves are left empty and water is injected at suitable intervals.—H. A.

Improvements in and relating to the Production of Potash from Potassium and Magnesium Carbonate. H. Precht, Löderburg, Germany. Eng. Pat. 4519, March 22, 1890, 4d.

The double salt, $\text{KHCO}_3 \cdot \text{MgCO}_3 + 4 \text{H}_2\text{O}$, is decomposed in a covered apparatus by heating with water under a pressure of at least half an atmosphere, and at a temperature above 115° C. A precipitate of magnesium carbonate is formed, and a concentrated solution of potassium carbonate remains. In practice it is best to work at about 140° C. and with a pressure of about 5 atmospheres. The carbonic acid evolved from bicarbonates of potassium and magnesium that were in solution at the beginning of the operation, can be obtained in this way comparatively free from water, as the solution does not boil at this pressure and temperature.—H. S. P.

Improvements in the Production of Magnesium Oxychloride. F. M. Lyte, London. Eng. Pat. 6333, April 25, 1890, 4d.

MAGNESIUM hydrate or magnesite is burnt at the lowest possible temperature, and mixed with 30—40 per cent. of more strongly burnt magnesia, and 15—20 per cent. of organic matter; an admixture of glass, silica, or slag will render the mass more coherent when burnt. The mixture is then formed into bricks, covered with a wet cloth till the mass begins to set, and the setting completed under water. The bricks are then gradually heated to redness and the remaining porous mass saturated with fused magnesium chloride. A magnesium oxychloride is then formed (this Journal, 1890, 622), which can be employed for the manufacture of chlorine (this Journal, 1890, 1128—1129).—H. A.

Improvements in the Manufacture of Chlorine. G. E. Davis and A. R. Davis, Manchester. Eng. Pat. 6698, May 1, 1890. *6d.*

In the specification for "Improvements in the Preparation of Chlorine," Eng. Pat. 6416 of 1890 (this Journal, 1891, 463), the fact that the water of the reaction flowed away from the first nitric acid tower holding a quantity of hydrochloric acid gas in solution, is mentioned. This water of reaction may absorb as much as 30 per cent. of the hydrochloric acid, and the total water introduced into and formed in the process may at times be capable of dissolving and so removing from the process nearly one-half of the hydrochloric acid produced from the salt. The invention described has for its object such a modification of the process, as will enable the operator to keep the whole of the hydrochloric acid employed within the process until its chlorine is liberated.

To this end the sulphuric acid which has passed down the absorbing tower for the purpose of absorbing nitrous compounds is now caused to enter the first nitric acid tower at a point below where the action of the nitric acid upon the

hydrochloric acid is completed, and where an excess of hydrochloric acid exists. The result is that the sulphuric acid at once combines with the water of the aqueous hydrochloric acid and the hydrochloric acid is liberated, a portion of it reacting upon the nitrogen oxides present in the sulphuric acid, forming chloronitrous gas, which passes on with the main body of the gases to be decomposed as already described in Eng. Pat. 6416 *loc. cit.* This improvement necessitates also the production of weak sulphuric acid, which is hereafter concentrated to the proper strength for the decomposition of salt or the absorption of nitrous gases.

Improvements in and Apparatus for or connected with the Liquefying and Storage of Chlorine. T. Y. Johnson, London. From J. Marx and Dr. Weller, Sachsenhausen, Germany. Eng. Pat. 7058, May 6, 1890. *8d.*

For the purpose of liquefaction, the chlorine is first of all separated in the form of hydrate from its admixture with other gases. This is effected by injecting water or

brine in a receiver, into which the chlorine is simultaneously admitted. The receiver is provided with a false bottom on which the chlorine hydrate collects, whilst the excess water drains through the perforations and is pumped back, after cooling, into the receiver.

After sufficient chlorine hydrate has been formed, the vessel is disconnected and the chlorine is liberated from its combination with water by the aid of heat, preferably water of 25° – 30° C., circulating through some piping placed inside the receiver. The evolved gas passes first through a vessel cooled from outside by water, and provided with a perforated bottom. Any water present deposits here in combination with chlorine; the escaping chlorine is collected in a water-jacketed or otherwise cooled storing bottle, in which it is liquefied by its own pressure.

The cast-iron or steel storing bottles are to a certain extent acted upon even by liquid chlorine, which is therefore preferably kept in glass bottles, having an iron jacket cemented to the outer surface. The glass bottles are provided with metal heads which, for the purpose of charging, can be screwed on to the iron bottles. Two drawings accompany the specification.—H. A.

Improvements in and connected with the Obtainment of Cyanides and Ferrocyanides. D. T. Playfair, Glasgow. Eng. Pat. 7764, May 19, 1890. 6d.

By heating in a retort an intimate mixture of an alkaline or an alkaline-earthly "sulphocyanate" (thiocyanate or sulphocyanide) with powdered zinc or lead, or with both of these metals, the corresponding cyanide is formed along with zinc or lead sulphide. The charge is heated above the melting point of zinc, and at the completion of the reaction the charge is withdrawn at once to prevent secondary reactions; there is less danger for these to take place when lead has been used instead of zinc. The mass is lixiviated and any undecomposed sulphide may be removed by addition of freshly precipitated cyanide of lead. The solution may either be used directly or else evaporated to dryness in vacuo. The lead or zinc are regenerated from the corresponding sulphides.

When ferrocyanides are required, a mixture of iron and lead or zinc is used; the iron sulphide formed in the process of fusion reacts with the alkaline cyanide with production of an alkaline ferrocyanide, which may be obtained in a crystallised form.

The sulphocyanide is preferably produced by the action of ammonia and carbon bisulphide in the presence of a fixed alkali or of an alkaline earth. The resulting solution is heated for the elimination of any ammonia present, filtered from the sulphur and evaporated to dryness.—H. A.

A Process for the Application of Iron Residues which result from the Reduction of Organic Nitro compounds. T. Peters, Chemnitz, Germany. Eng. Pat. 8922, June 9, 1890. 6d.

THE iron residues of the aniline works consist chiefly of iron sesquioxide, with an admixture of carbonaceous matter, in suspension in a liquid containing calcium chloride. It is proposed to utilise these residues for the manufacture of liquid or solid iron mordant. 200 parts of the well-settled iron-mud are treated with 100 parts of "moderately dilute" sulphuric acid or preferably waste acid from the nitration of the aromatic hydrocarbons, and 100 parts of water are added. A violent reaction soon sets in, whereby the whole mass liquefies and the bulk of the organic matter is destroyed. The mass is allowed to settle, the clear liquor is drawn off and evaporated to 50° Tw. A product free from iron protoxide may be obtained by adding dilute nitric acid during the process, for which purpose the weak acid from the manufacture of nitric acid may be used.

The remaining iron-mud is washed with water, and the washings used over again in lieu of water.

For the production of iron mordant in the solid state 100 parts of the mud are mixed with the same quantity of

"fairly concentrated" sulphuric acid or waste acid. The mixture solidifies to a hard mass which is easily pulverised.—H. A.

Improvements in the Manufacture of Caustic Soda. F. Ellershausen, Hebburn-on-Tyne. Eng. Pat. 9112, June 12, 1890. 4d.

SODIUM ferrate, preferably in the hot state, as it is drawn out of the furnace, is laid in an open tank in a layer about 4 ft. thick. The sodium sulphide liquor is run on the centre of the filter surface and is causticised as it penetrates through the mass. The sides of the vessel are thus protected from the corrosive action of the sodium sulphide liquor. (See Eng. Pats. 1015 and 1016 of 1890, pages 253 and 543.)—H. A.

Improvements in the Process of and Apparatus for Purifying Double Carbonate of Potassium and Magnesium. H. Precht, Loderburg, Germany. Eng. Pat. 10,115, June 30, 1890. 8d.

THE double salt $MgCO_3 \cdot KHC O_3 \cdot 4H_2O$, prepared by Engel's process, viz., by treating a solution of potassium chloride with magnesium carbonate and carbonic acid under pressure, contains a certain amount of impurities in form of magnesium chloride and potassium chloride, which prevent the manufacture of pure potassium carbonate therefrom. The patentee finds that impurities can be reduced to 0.2–0.3 per cent. by washing with a solution of magnesium carbonate in water containing carbonic acid. The washwaters are then saturated with potassium chloride and return to the process.—H. A.

Improvements in the Manufacture of Chromates, Bichromates, and other Chromium Compounds. H. H. Lake, London. From J. Massignon and E. Watel, Paris, France. Eng. Pat. 2224, February 6, 1891.

THE object of this invention is to obtain a complete decomposition of the chrome ore with economy of fuel. The finely ground chrome ore is mixed with a paste prepared by slaking more than a sufficient quantity of lime or limestone, or a mixture of both, to form calcium chromate, in a strong solution of calcium chloride, containing one equivalent of calcium chloride for three equivalents of the lime employed, "which proportion is suitable for composing calcium oxychloride." The kneaded mass is formed into blocks, dried, burnt in a kiln heated by gas, and partially oxidised by a current of air which passes through the kiln. The baked materials are then piled up in aired chambers where the "complete oxidation" of the chromium sesquioxide is "gradually effected" by the atmospheric oxygen.

For manufacturing chromic acid, chromates and bichromates of potash or soda, the calcium chloride contained in the oxidised mass is first extracted with hot water, and the small quantity of calcium chromate contained in this solution is either precipitated with a lead salt for the manufacture of lead chromate or the whole solution concentrated and used for saturating a fresh quantity of chrome ore and lime. After this washing operation, the remaining mass is treated with sulphuric acid, if chromic acid be required, or with potassium or sodium carbonate or sulphate and sulphuric acid for the manufacture of the corresponding bichromates. The dry oxidised material may be treated direct by sulphuric acid or by hydrochloric acid gas for the production of chlorochromic acid.—H. A.

Process for Converting Carbonate of Lead, obtained by Decomposition of Sulphate of Lead or other Compound of Lead with Carbonate of Sodium, into Basic Salt. J. N. Zeitler, Cannstatt, Germany. Eng. Pat. 2812, February 16, 1891. 4d.

See under XIII., page 557.

Improvements in the Manufacture of Phosphorus in Sticks or Blocks. W. P. Thompson, Liverpool. From "La Société Cognet & Co.," Lyons, France. Eng. Pat. 2970, February 18, 1891. 4d.

The phosphorus is formed in rectangular parallelepipeds which will fit one on the other along their lateral faces. The packages will thus hold more phosphorus, and only about one-fifth of the water will be required for filling up the empty space in the packages, in comparison with the quantity necessary when packing cylindrical or prismatic phosphorus.—H. A.

VIII.—GLASS, POTTERY, AND EARTHENWARE.

PATENTS.

Improvements in Ovens for Firing Pottery. A. J. Wilkinson, Burslem. Eng. Pat. 4356, March 20, 1890. 8d.

The object of the patent is the attainment of a more even temperature than can be got in the ordinary pottery kiln.

This is achieved by the use of vertical flues between the "bags," the lower ends of which pass horizontally through the bottom of the oven, while the upper ends are about level with the outside top of the crown of the oven. The flues converging from the bags to the "wall hole" may be partially divided longitudinally for the better distribution of the heat. Any suitable number of holes situated in the cone of the oven and provided with means of regulating the draught may be used.—B. B.

Improvements in Coke Ovens, and in the Method of Using the same. F. Edwards, London. From F. Strochmer, Dresden, Germany. Eng. Pat. 4457, March 21, 1890. 8d.

See under H, *supra* 531.

Improvements in the Manufacture of Ceramic Ware and Apparatus for that Purpose. H. M. Ashby, Ferrybridge. Eng. Pat. 5970, April 19, 1890. 6d.

The raw plastic material of which the ware is to be made is forced through a die so as to form a sheet. Both surfaces of the sheet are pretentively partially dried by currents of warm air, and are sprinkled with some of the material of which the sheet is composed in the state of powder. The sheet then travels between rolls or over guide rollers to a punch, which cuts out and removes a disc from the sheet. The disc held by the punch is brought over a mould and air or other fluid under pressure is admitted at the back of the former, forcing the disc into the latter and causing it to receive its form. The mould is then inverted and the shaped disc either dropped or forced out by compressed air, on to a travelling apron by which it is finally removed.

The method is applicable to the manufacture of such articles as plates, saucers, and basins.—B. B.

Improvements in Kilns. F. Brook, Huddersfield. Eng. Pat. 6088, April 22, 1890. 8d.

It is proposed to provide a bottom supply of gas and air in gas fired down-draught kilns. A gas flue is arranged near the bottom of the kiln with perforations for admitting gas near to the walls and the lower part of the kiln where it meets with air.

The products of combustion after circulating through the kiln pass away through perforations in the floor to a discharge flue.

A number of these kilns adopted to be worked in rotation can be worked regeneratively.—D. A. S.

An Improved Method for Producing Coloured Designs on Glass. O. Billmann, Munich, Germany. Eng. Pat. 9942, June 26, 1890. 6d.

The object of the invention is to produce glass with coloured designs in which a greater variety of colours may be obtained at less cost than by the usual method, and this object is attained by placing together two panes of single flashed glass differently etched, so that the coloured part of one frame may coincide with the plain part of the other. A further variety may be obtained by allowing two etched portions to coincide, whereby a portion of the design will appear in clear glass.—B. B.

Improvements in Lears for Annealing Sheets of Glass. G. F. Chance and Chance Bros. and Co., Lim., West Smethwick. Eng. Pat. 12,212, August 5, 1890. 11d.

An ordinary "lear" consists of an arched tunnel, kept heated from one end by suitable furnaces, and through which the sheets of glass to be annealed are caused to travel with an intermittent motion. With a view of quickening the rate of working, the patentees have devised a double tunnel, the two parts being wholly or partly separated by a vertical wall, which is heated in the ordinary way and has at the furnace end where the sheets of glass are introduced a "push hole chamber," forming an entrance to the "cooling chamber" as is usual.

The mechanism for conveying the sheets of glass from one end of the lear to the other is of the ordinary type and calls for no special description. The cooling chamber of one tunnel communicates directly with that of the other, and the push hole chamber may be on either side of the pair of tunnels. The sheets of glass are introduced by the push hole chamber into the cooling chamber and shifted on alternately into the two tunnels, which they traverse, and at the ends of which they are withdrawn also alternately.

Instead of two distinct tunnels one of double the ordinary width may be employed.—B. B.

Improvements in Kilns for firing Fire-bricks, Earthenware, and the like. J. Dunnachie, Glenboig. Eng. Pat. 17,573, November 3, 1890. 8d.

This patent relates to improvements in the kilns described in Eng. Pat. 3862 of 1881. The arrangement of kilns used by the patentee consists of a number of chambers or kilns used in rotation with regenerative heating by means of producer-gas. The object of the present patent is to introduce into each chamber, as may be required, a number of comparatively small jets of gas for driving off the moisture of the articles to be fired. This end is attained by the use of two small supply flues under the floor of each chamber, which open into the chamber by numerous small tubes, called "steaming holes" by the patentee. "Hopper furnaces" burning solid fuel may be substituted for those adapted for producer gas, the other arrangements being similar to those employed in the complete rotation system.

—B. B.

Improvements in Implements for Cutting Glass Tubes. A. F. Hunt, Scranton, U.S.A. Eng. Pat. 3607, February 27, 1891. 8d.

The implement consists essentially of two parallel arms, attached to each other at one end by a bow, spring, pivot, or hinge, one of which is provided with a replaceable bevel cutter, and the other with a concave segmental clamp. A stop-piece travels on the arm bearing the cutter, and is provided with a set screw, by means of which it can be fixed on the arm at a predetermined spot. This arm is also graduated. The method of operating consists in inserting the cutting arm into the tube to be divided as far as the stop-piece, which latter has been set at a distance from the cutter equal to the length of tube it is desired to cut off. The arms are then brought towards each other by

hand or by some simple mechanical device such as a screw or sliding collar embracing both, so as to press the cutter against the inside of the glass tube at the exact spot where the concave support is pressed against the outside. On rotating the tube thus clipped between the cutting and the supporting jaw, a circular cut is made in it, and it can easily be broken off neatly by gently tapping. The patent describes many possible modifications of the implement.—B. B.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

Antiseptic Treatment of Building Materials. Résumé by E. Dollfuss of a communication from V. Boyet. Bull. Soc. Ind. Mulhouse, 1890, 546—549.

See under XVIII. C., page 563.

The Effect of Preservative Agents on Mine-Timber. Compt. Rend. Mensuels de la Soc. de l'Ind. Min. 223, November 1890; and Proc. Inst. Civil Eng. 1891, 104, (ii.) 74.

At Saint-Eloy in Anvergne, experiments on the effect of antiseptic agents on the duration of timber underground, have been carried on since 1879, upon the following description of timber:—

1. Oak from the Allier..... 35 years old.
2. Oak from the Nièvre..... 27 years old.
3. Fir from the Allier..... 22 years old.
4. Pine from the Allier..... 20 years old.
5. Birch from the Allier..... $5\frac{1}{2}$ in. diameter.
6. Beech from the Allier..... $5\frac{1}{2}$ in. diameter.
7. Poplar from the Allier..... $5\frac{1}{2}$ in. diameter.

Method of Treatment.—A stem of each description of wood was sawn into 52 discs, each $\frac{3}{4}$ in. thick, the first and last of which were preserved in their natural condition above ground in the open air, but protected from damp, the remaining 50 were placed in a kind of cage in a damp level underground, where the prevailing temperature was about 75° F. Two discs in each 10 were left unprotected, while the remainder were subjected to treatment by the following substances:—

1. Sulphate of iron.
2. Sulphate of copper.
3. Chloride of zinc.

The strength of the solutions varied from 100 to 450 grms. of the salt to 1 litre of water, and the period of immersion from one hour to 40 days.

4. Creosote, of the impure commercial kind, immersed for similar periods.

5. Painted with three coats of the following oil colours: Pure white lead, white lead and yellow ochre, white lead and emerald green, red lead, white lead and lamp black, white lead and prussian blue.

6. Tar, mineral and vegetable, immersion for five minutes.

After preparation, the samples were kept in the office at the surface for 50 days before exposing them underground, and they were subsequently examined at five different periods—namely, six months, one and a half year, two and a half years, three and a half years, and eight and a half years, the amount of alteration being laid down on a diagram which accompanies the paper. From this it appears that the unprotected specimens were almost all destroyed in a comparatively short time—two and a half years to three and a half years—the observed order of durability being as follows:—

- No. 1. Beech.
- No. 2. Oak No. 1.
- No. 3. Poplar.
- No. 4. Oak No. 2.

- No. 5. Birch.
- No. 6. Fir.
- No. 7. Pine.

The preservative effects of the different substances employed is given in the following table, which represents the increase in the duration of the protected specimens in terms of that of the unprotected ones, the latter being taken as unity.

	Oak.	Oak.	Fir.	Pine.	Beech.	Birch.	Poplar.
	No. 1. No. 2.						
Tar	28.7	24.6	263.5	87.5	105.4	23.2	150.5
Chloride of zinc.	10.5	9.2	50.0	26.3	18.6	52.5	34.7
Oil paint	6.1	10.2	31.7	54.5	25.0	12.1	2.5
Sulphate of copper	42.1	26.4	12.0	8.0	1.8	2.5	15.5
Sulphate of iron.	18.0	12.5	12.1	4.2	4.7	3.5	2.9
Creosote	1.7	0.9	2.5	4.4	0.6	3.3	1.3

PATENTS.

Improvements in Coating Iron, Steel, or other Metals or Materials with Portland or other Cement. C. Kellner, Vienna, Austria. Eng. Pat. 6952 May 6, 1890. 6d.

See under XIX., page 566.

Improvements in the Manufacture of Artificial Stone. J. Hartnell, Cardiff. Eng. Pat. 8413, May 30, 1890. 6d.

THREE pounds of sugar of lead, 4 lb. of alum (powdered and burnt on an iron plate placed over a fire), 4 lb. of "common soda" (also previously heated), 2 lb. of powdered bluestone are "immersed in 30 gallons of cold water," and 8 lb. of oil of vitriol added. After the reaction has ceased and the mixture cooled, the resulting solution is added to a mixture of crushed stone (preferably granite), 3 parts; gravel, 2 parts; and "cement," 1 part, all by weight, in the proportion of 1 gallon to $14\frac{1}{2}$ cwt. of the dry ingredients, the wetting being done by degrees, and the superfluous moisture being gradually patted to the surface.

The composition may be used for breakwaters, dock walls, pavements, stairs, mantelpieces, &c. In laying a pavement, a foundation consisting of 2 in. of lime concrete is first made, allowed to set for a day, and then the patented mixture laid on to the depth of 2 in. It may be used for foot passengers in one day, and vehicular traffic after a week. Moulded articles such as window sills may be removed from the moulds after one day, and fixed at the end of a week.—B. B.

Improvements relating to the Production of a Plastic Moulding Material and to Articles made therefrom. H. H. Lake, London. From E. Sochaczewski, Waltershausen, Germany. Eng. Pat. 3365, February 24, 1891. 4d.

ONE part of French or Cologne glue is dissolved in 3 parts of water by the aid of heat; $1\frac{1}{2}$ parts of burnt marble or "pure or mixed minerals, such as porcelain material," and $1\frac{1}{2}$ parts of burnt gypsum are added with continuous stirring.

In casting this composition the moulds are cooled both before and after the operation. "When the finished articles are to be employed in hot chambers, it may be expedient to add about $\frac{1}{4}$ part of eolophony or other resin in the molten state," but this is not claimed as novel.

The material is said to be hard, strong, and cheaper than unmixed plaster of Paris.—B. B.

X.—METALLURGY.

Zinc Desilverisation. H. Roessler and B. Edelmann.
Eng. and Mining J. 1891, 51, 104—106.

THE authors' desilvering scheme of treating the silver-lead maintained at 600° with successively increasing quantities of zinc, and allowing each portion of the latter metal to pass through four times, proves successful on small quantities of pure silver-lead. The oxidation is only slight, and a product is obtained which can be worked up directly without previous liquation. But in operations on a large scale with base bullion of commerce, containing copper, arsenic, and antimony, oxidation is considerably increased and a scum difficult to separate is obtained, necessitating such a rise of temperature that much of the silver passes back into the lead during the first skimmings. Therefore, although the desilverisation is ultimately achieved, yet the advantage is not as great as anticipated from the experiments with pure silver-lead. It is now observed that the addition of 1 or even 0.1 per cent. of aluminium to the zinc impedes oxidation in pure silver-lead, but in the case of ordinary impure silver-lead the amount of aluminium required becomes too costly. Copper seems the chief cause of the oxidation in the zinc-carrying lead, for the protective action of aluminium becomes more evident with base bullion after copper has been removed by some zinc. Results tabulated in the paper demonstrate that the first additions of zinc serve to remove useless impurities and to contribute to the lead the proportion of zinc required to remove the silver present. It was therefore next tried to both saturate and desilverise the lead with one addition of zinc, and in order to ensure the saturation it was found necessary to add the requisite proportion of zinc in a molten state to red-hot lead; for although the higher temperature is more favourable to oxidation, yet when it is employed less stirring is required, and the concomitant exposure of fresh surface for oxidation is proportionately diminished. In fact, with aluminium added to the zinc, oxidation is then almost entirely obviated. Under these circumstances the zinc dissolves completely, and in gradually cooling reappears as a scum carrying with it all the silver, which can be thoroughly melted out. With impure silver-lead, as in the previous experiments, a preliminary removal of the copper is required to ensure success, which in all cases depends on retaining the proper proportions of zinc and the correct temperature. If the latter is too high oxidation takes place and irregular results are obtained. Richer skimmings, as referred to in the first paragraph, are obtained under these circumstances by using the poorer or second skimmings of a previous experiment as part of the charge of zinc. For example:—

	Grams. of Silver
To 100 parts of lead melted with	450
are added, ... 1.2 parts of zinc	130
and, ... 1.4 parts of zinc in skimmings with	130
In all, ... 2.6 parts of zinc with	280
Skimmed off are	
... 0.6 parts of zinc with	150
and, ... 1.3 parts of zinc with	130
Leaving ... 0.6 parts of zinc with the lead.	

When copper is present, it is removed by zinc in a preliminary small skimming, which runs high in copper, but low in silver. (See also this Journal, 1890, 1133—1134.)
—D. A. L.

Wolfram Mining in New Zealand. Otago Daily News.

A RECENT cablegram stating that German firms are inquiring if wolfram is procurable in Australia, and offering to take a large quantity, should reopen a neglected though important mining industry in Otago, which is perhaps richer in that particular metal than any other locality in the world. Wolfram, or tungsten, belongs to a group of rare metals, and till a comparatively recent time was known only to the chemist, and its value was only in the laboratory. With the invention of 100-ton guns the demand for tungsten soon made that previously obscure

metal well known throughout the mining world. It was soon found that the steel tube lining the bore of these enormous guns could not resist the shock entailed by discharging many shots without becoming fractured, when of course an expensive piece of ordnance became useless. Experiment proved that the addition of a small quantity of tungsten to the fine steel employed in gun-making rendered the latter metal wonderfully elastic, so that the steel tube will expand under the tension of firing and contract again to its normal size a great many times before the quality of the metal is in any way impaired. The German gun factories consequently absorb most of the tungsten found in the world, and from being a mere curiosity seen only in the laboratory of the chemist, this rare metal has acquired considerable value. Wolfram (erroneously called tungstate of iron in the cablegram) generally occurs in combination with iron in Europe, but is also found in scheelite, or tungstate of lime. It is in the latter form that it occurs in Otago. The metal itself is of a white colour, extremely brittle, and heavy, the specific gravity being 19.1, that of gold being 19.3. It will thus be seen that tungsten is a very heavy metal, being only very slightly lighter than gold.

PATENTS.

Improvements in Cleaning and Annealing Iron and Steel, and Apparatus therefor. G. C. Fricker, Putney. Eng. Pat. 1369, January 25, 1890. 8d.

THIS patent refers to the cleaning of iron sheets, wire, &c. previous to tinning or galvanising the same. Instead of the usual pickling solutions for removing the scale the patentee employs hydrogen or other similar gas containing hydrogen, such as coal-gas or sulphuretted hydrogen. The materials are heated to a very high temperature in a chamber enclosed in a furnace, and into which the gas is led from a gas-holder, and whence the steam and unused hydrogen are conveyed to a condenser. The steam is condensed and the excess of hydrogen recovered. Various plans are adopted and described for conveying the hydrogen to and from the heated materials, such as using a fan or blower, allowing fresh hydrogen to be drawn in by the rarefaction resulting on the condensation of the steam, or by using two gas-holders and by alternating the pressure passing the gas backwards and forwards through the reducing chamber from one to the other. There are 11 illustrations in the specification. The necessary hydrogen is preferably prepared by passing steam over iron clippings heated to redness.—A. W.

Improvements in or relating to the Treatment or Utilisation of Scrap Tin or Tin Plates and the like. W. P. Thompson, Manchester. From E. Carrez, Brussels, Belgium. Eng. Pat. 1913, February 5, 1890. 6d.

THE process is one for removing the tin and lead from tin plates without injuring the iron of the plates, and for the recovery of the tin. The plates are treated with a concentrated solution (of about 30 B.) of the "polysulphide of sodium obtained either from the sulphurets of sodium residues from the Leblanc soda manufacture or from the polysulphides of calcium mixed with hyposulphite of calcium, which is transformed by means of carbonate of soda into sulphuret and hyposulphite of soda, or from the sulphurets of sodium mixed with a little nitrate of sodium resulting from the manufacture of nitrate of barium by means of sulphide of barium and nitrate of sodium, or from any other sulphuret of sodium," by boiling the sulphides with a slight excess of sulphur. The plates are dipped in this solution, which is heated by steam to from 50—70° C., and to which has been previously added a little ammonium chloride. The addition of ammonium chloride counteracts the solubility of sulphuret of iron in the polysulphide of sodium solution, "and even any attacking of the metallic iron by the alkaline sulphide." After being dipped for three or four minutes the plates are washed with water. The lead is removed by the alkaline sulphide solution, and precipitated as sulphide whilst the tin goes into solution. When the polysulphide solution is saturated with tin it is decanted, and the tin recovered from it in a suitable way.—H. S. P.

Improvements in the Reduction of Metallic Ores. G. Simonin, Li Bourne, France. Eng. Pat. 3275, March 1, 1890. 4d.

THE improvements relate to the treatment of ores of antimony, and of zinc. The sulphides, carbonates, and other ores of these metals are roasted with reducing agents in a revolving reverberatory furnace, heated by gas-fuel. The gases and matters passing from the furnace enter a chamber filled with coils of pipes in which the air used for the combustion of the gas-fuel becomes heated. From this chamber the gases then pass into a second chamber or series of chambers, in which they become further cooled and the metallic oxides volatilised in the furnace become deposited. In order to recover the whole of the oxide the gases are then passed through a scrubber. If it only be desired to reduce the sulphides or carbonates to oxides without driving off the oxides, a lower temperature is used in the furnace, and the reducing agents are omitted.—H. S. P.

Improvements in or relating to Blast or Smelting Furnaces having Water-Jackets. J. W. Chenhall, Totnes. Eng. Pat. 2544, February 17, 1890. 8d.

THIS is a method of constructing blast furnaces for lead or other ores to enable the lower jackets to be easily removed for inspection and repairs. The specification is illustrated with drawings, and a way of making the tuyere openings so as to avoid any joints being exposed to the fire is described.—D. A. S.

Improvements in the Manufacture of Copper. H. H. Vivian, Swansea. Eng. Pat. 6821, May 2, 1890. 4d.

THE impurities are dissolved out of the finely-divided oxidised compound by an organic acid. When the material is metallic copper it is melted, granulated, and roasted, and the oxide finely ground. When it is a matte it is first ground and then roasted. Towards the end of the roasting a little salt may be added and well mixed with the charge, as it facilitates the extraction afterwards. The resulting copper oxide is lixiviated with a solution of tartaric acid, which dissolves out the arsenic, antimony, gold, silver, and other foreign substances, leaving a residue which, upon reduction with carbon in a reverberatory furnace, yields a copper of high quality. The quantity of acid used for every ton of oxide is about 2 lb. dissolved in 200 lb. of water. It is not essential that the matte be roasted, for it will be much improved if it is finely powdered and treated direct with the acid, and will yield a purer copper. The solution after lixiviation is submitted to the action of an electric current through insoluble anodes, by which means the dissolved metals are deposited and the acid liquor left ready for a second usage. Citric, acetic, and oxalic are the other organic acids claimed.—A. W.

Improvements in the Manufacture of Steel-plated and Gated Ingots, and in the Moulds for Same. J. Neill, Sheffield. Eng. Pat. 6960, May 6, 1890. 8d.

THE present method of making combination ingots, technically known as "gated" or "plated" ingots, consists of first casting the low quality steel which forms the bulk of the ingot, quickly removing a side plate and substituting another one with the necessary cavity and pouring in the higher class steel, which welds itself to the hot face of the previously cast metal and forms a compact solid combination ingot with a hard steel corner or face. This latter portion is generally permeated with minute holes, which, on working are to some extent removed, but which still remain imperfections. The patentee's object is to overcome this drawback by casting the steel "gate" first, and his specification relates to specially-constructed ingot moulds, of which and their parts there are 12 illustrations. In the case of the gate mould the portions of the two sides which constitute the gate corner are made some inches higher than the top of the remainder of the mould. Into this corner is placed a right-angled plate, which is fixed tightly by a ring and wedge against these two extended pieces—thus forming

a corner mould inside a larger one. The lower end of this angle-plate is kept in position by a shoulder cut in the base of the mould, where also there is a second and lower shoulder which keeps the cast gate piece erect, and prevents it falling across the mould, when the angle-plate is removed. The high quality steel is first cast in this corner mould, and the angle-plate being quickly removed mild steel or iron is run in to fill up the remaining bulky space of the large mould. By this means improved castings are said to be obtained, especially in respect to the steel corner; moreover the corner piece is longer than the bulk of the ingot, and forms a topping head.—A. W.

Improvements in the Manufacture of Steel and Iron and in Apparatus to be employed in such Manufacture. J. Heaton and G. H. Holden, Manchester. Eng. Pat. 7070, May 7, 1890. 1s. 1d.

THIS patent relates to some mechanical improvements and arrangements in the Heaton process of converting cast iron into steel by the use of nitrates or chlorates (Eng. Pats. 798, 1866, and 1295, 1867). The iron is melted in a cupola and run into a measuring vessel or receiver, whence it is run through a plugged or valved passage into the converter. The converter is divided into two portions, the upper and the lower. The former is a kind of chimney open at the base, and the latter consists of a removable vessel in which is placed the nitrate. This vessel or kettle is supported by trunnions on a truck running on rails and consists of an iron casing lined with refractory material and with a circular perforated plate which is fixed in position above the nitrate. When ready the whole of this lower portion of the converter is run on to the table of a hydraulic ram underneath the upper portion, and the two parts are pressed and clamped tightly together. The molten cast iron is then introduced from the measuring vessel. The upper portion of the converter is so arranged that the gases may be led to a condensing chamber and by-products obtained therefrom. The specification contains eight claims and 15 drawings.—A. W.

A Process and Apparatus for Reduction of Iron and other Oxide Ores and for Fusion and Purification of the Produced Metals. J. D. Danton, Paris, France. Eng. Pat. 7129, May 7, 1890. 8d.

THE apparatus consists of a tall circular furnace divided into concentric compartments. The centre one receives the reducing gases and is separated by a perforated wall from an annular compartment into which the ore is supplied from the top. This compartment is separated by another perforated wall from an outer annular chamber, into which the gases pass after having traversed laterally through the ore from the innermost chamber. The reducing gases may be prepared and heated elsewhere, or they may be generated in a producer placed at the base of the central compartment. The ore falls through the second compartment, wherein it is partially reduced in its descent by the transverse currents of gases, and is withdrawn from below. The reduction is completed by fusion with bituminous coal in another furnace. The outer chamber may contain air or water tubes for utilising the heat of the waste gases before they are finally expelled. There are five drawings illustrating various modifications of furnaces involving the same principle. The explanation of the reduction by carbon monoxide is that the gas is decomposed, one portion of its carbon taking up additional oxygen and passing off as carbon dioxide, while the other portion is deposited in the pores of the ore ready to operate in the final portion of the reducing process. The operation relates principally to the ores of iron.

The molten metal is refined immediately it is tapped by allowing it to descend in a shower through a heated chamber having perforated walls, wherein it is exposed to streams of air carrying in suspension any powders suitable to the metal, such for instance, as silica, which produces a slag and eliminates the phosphorus. There are 12 claims in the specification.—A. W.

The Application of Water-Gas to the Manufacture of Iron and Steel, in connection with Siemens and other Gas Furnaces. S. Fox, Leeds. Eng. Pat. 7827, May 20, 1890. 81.

The object of the patent is to mix water-gas with the ordinary Siemens or producer gas used in the manufacture of iron and steel, so that the temperature necessary and the elimination of the impurities of the metal may be more readily attained.

Drawings are shown in the specification of a Siemens gas furnace, a puddling furnace, and a crucible furnace, the water-gas being in all cases introduced by jets or nozzles so disposed as to mix with the air and producer gas supplying the furnaces.—B. R.

A Method of Extracting Gold from Auriferous Ores by an Improved Process of Amalgamation, and Apparatus therefor. J. W. Macfarlane, Cathcart. Eng. Pat. 8884, June 9, 1890. 11d.

This specification contains 15 claims and 18 drawings. A cylindrical vat is revolved at high speed on a vertical spindle in the centre of its base. Mercury is placed in the vat and by the centrifugal action spreads itself evenly on the inner surface and so forms a vertical wall of the liquid metal, which acts as the amalgamating surface. The finely-ground ore is washed into the centre and bottom of the vat and is made to pass over the surface of the mercury and to rise up and overflow at the top edge. Various appliances and mechanical devices for preventing the ore from becoming stationary and to cause it to pass in a thin continuous stream over the mercury, are fully described in the specification. In the treatment of some kinds of ores "a diluted solution of calomel in aqua regia" is charged in with the ore for the purpose of assisting the amalgamation.—A. W.

A New or Improved Process for the Utilisation of Oxide of Iron obtained as a By-product in the Smelting and Extraction of Copper from Pyrites, or from Spent Oxide produced in the Manufacture of Sulphuric Acid. J. Broadbury, Manchester. Eng. Pat. 10,062, June 30, 1890. 1d.

The residue of oxide of iron from burnt pyrites and copper extractions is treated with hydrochloric acid in a suitable vessel provided with a steam coil for heating the same. An excess of oxide must be present, and the mixture is heated until the acid is saturated. A little nitric acid should be added if any ferrous oxide be present. The solution of ferric chloride so obtained is then used, either alone or with other materials, such as lime or alkalis, for the purification of water, sewage, &c., for making oxide of iron paint, or Prussian blue, and for the decoloration of sugars and syrups.—A. W.

Improvements in the Process of Treating Metalliferous Ores. I. H. Mohswoth, Adelaide, Australia. Eng. Pat. 13,723, September 1, 1890. 8d.

The patentee roasts sulphide ores containing gold and silver by heating them in a calciner and submitting them to the action of air and nitrogen peroxide, the advantage being that the operation is more rapid and is performed at a low temperature. The apparatus consists of a revolving calcining cylinder heated externally and fed with ore by a screw from a hopper at one end. At the other end the ore comes together with the products of the decomposition of crude nitre by sulphuric acid which are brought there by a pipe from a retort placed above the cylinder. The gases from the calciner are drawn by means of an exhaust fan through a so-called condensing chamber. The nitrogen peroxide from crude nitrate of soda contains much chlorine, so that the acid which condenses in this chamber is "nitro-chloro-hydrochloric acid." This liquid is then placed in a vat with the roasted ore to extract the gold therefrom. In this operation nitrogen peroxide is regenerated, and is fed to the

mouth of the calciner for repeated usage therein. Its function in the roasting operation is to oxidise the last traces of sulphur and arsenic in the ore. One ton of pyrites for roasting by this process and subsequent extraction of the gold requires "about 8 lb. of nitrate of soda and 4 oz. of sulphuric acid."—A. W.

Improvements Relating to the Treatment of Slag, and to the Removal thereof from Furnaces. O. B. Peck, Chicago, U.S.A. Eng. Pat. 15,311, September 27, 1890. By Internat. Conv. March 3, 1890. 6d.

This is a patent for a method of carrying off furnace slag by dividing it into small particles by centrifugal action and pumping it away mixed with water. The apparatus consists of a circular pan supported in the centre of its base by a vertical revolving shaft and enclosed in a larger outer vessel into which water, steam, or spray can be injected. The molten slag is run into the revolving pan, whence it flies out in small spheres into the larger one, in which it is rapidly cooled by the water spray. The small pellicles are then withdrawn with the water through pipes by the aid of a centrifugal or other force pump and driven onwards through other pipes to the place of deposit.—A. W.

Improvements in Apparatus for the Treatment of Slag. O. B. Peck, Chicago, U.S.A. Eng. Pat. 15,312, September 27, 1890. By Internat. Conv. March 3, 1890. 6d.

This patent is the same as the preceding one, with the addition of a self-acting trap which is placed in the conduit pipe connecting the granulating vessel with the pump. It is so constructed that if the pump becomes clogged the slag will accumulate on the trap and force it down, which action will by the aid of a cord simultaneously close the pipe and open a second one leading to another force pump.—A. W.

Improvements in Centrifugal Apparatus for Treating Molten Material. O. B. Peck, Chicago, U.S.A. Eng. Pat. 15,343, September 27, 1890. By Internat. Conv. March 3, 1890. 8d.

This invention relates more particularly to the construction of the curbing that surrounds the receiving vessel, and to providing means for protecting its interior. The curbing surrounding the receiving vessel is constructed of two cast-iron plates, preferably provided with annular flanges. These plates form the top and bottom of the curbing, and are held together (preferably) by sheet iron riveted to the flanges. To prevent the curbing being injured by the molten metal thrown off from the receiving vessel, a cast-iron lining, preferably made in sections, is provided, and placed over the interior of the wall of the curbing.—E. S.

Improvements relating to Centrifugal Apparatus for Treating Molten Material. O. B. Peck, Chicago, U.S.A. Eng. Pat. 15,348, September 27, 1890. By Internat. Conv. March 3, 1890. 8d.

This invention is intended to provide convenient means for developing and applying the operating power, and for adjusting the various parts of the apparatus to each other.

In combination with a centrifugal machine, a bed plate or frame is constructed of a suitable length and breadth. One end of this frame carries the receiving vessel, curb, &c., and the other end the engine plate, to which is attached the engine and driving wheel, which is mounted directly on the engine shaft in a horizontal position, thus allowing a compact arrangement of the machinery and the use of a short, straight belt to connect the driving wheel with a pulley on the shaft of the centrifugal machine. This belt can be adjusted by moving the engine-plate backwards or forwards by a hand-wheel and screw-thread shaft. Other means are added for obtaining the proper amount of pressure on the belt as may be necessary from time to time.—E. S.

Improvements relating to Centrifugal Apparatus for Treating Molten Material, and to Means for Removing the said Material from such Apparatus. O. B. Peck, Chicago, U.S.A. Eng. Pat. 15,349, September 27, 1890. By Internat. Conv. March 3, 1890. 6d.

THE object of this invention is to provide simple means for treating and removing the molten material, and also for removing any gas or steam that may be formed.

The bottom of the curb is connected by a pipe with a centrifugal pump, which forces the material from the curb to any desired point. To prevent the pump being clogged with lumps of the material, crushing rollers provided with cog-wheels are used. In order to carry off any gas or steam that may be formed a "suction fan" is employed. The pump, fan, and rollers are actuated by the ordinary machinery.—E. S.

An Improvement in the Manufacture of Cast Iron. J. B. Renshaw, Hartford, U.S.A. Eng. Pat. 16,724, October 21, 1890. 4d.

"This invention is applicable to the treatment of grey iron as used in foundries; and it consists in a process of eliminating, from melted iron, surplus graphitic carbon, and also a substance resembling carbon, which is called 'kish,' and is also produced in blast furnaces, and which, when in excess, causes kishy unsound surfaces on castings." The excess of carbon is removed by treating the melted iron with finely-divided iron oxide. The novelty consists in impregnating "sawdust, shavings, straw, or other vegetable fibre, of which the wood material used by upholsterers and called 'Excelsior' is a good variety," with the finely-divided iron oxide. To do this the fibrous material is moistened with water and the iron oxide is then thoroughly mixed with it, and the fibre is afterwards dried. When used, a quantity of from 1 to 3 lb. of the impregnated fibre for every 100 lb. of iron is placed upon the iron before it is melted, or mixed with the iron when it is melted, or placed in a ladle into which melted iron is to be poured. The fibre burns away leaving the iron oxide free to act upon the carbon in the iron.

—H. S. P.

Improvements in and Connected with the Galvanising of Sheet Metal. Davies Bros. & Co., Lim., and M. Bayliss, Wolverhampton. Eng. Pat. 18,066, November 10, 1890. 11d.

THE object is to dispense with manual labour in the conveyance of the iron sheets from the cold rolls, used by the patentees (this Journal, 1889, 898), through the galvanising bath and onwards through brushes, &c. The sheets pass from the cold rolls through a pair of small rolls one above the other near the edge of the bath, down guides to another pair of rolls revolving side by side just above the flux pot. The latter rolls push the sheets through the metal bath along guides to another set of side by side rolls, which withdraws them. To prevent interference with the proper crystallisation of the coating metal these withdrawing rolls are provided on their surface with corresponding studs. The sheets are then guided on to a system of grooved drums, the first of which is studded on the outer curves of the corrugations, with endless chains or wire ropes carried within the grooves by which they are taken to another set of rolls, the brushes, and delivered cold and ready for handling.—A. W.

XI.—ELECTRO-CHEMISTRY AND ELECTRO METALLURGY.

PATENTS.

Improvements in the Production of Ductile Iron from Cast Iron. H. H. Lake, London. From S. H. Emmens, Emmens, U.S.A. Eng. Pat. 17,627, November 5, 1889. 8d.

THE invention relates to producing ductile iron from ordinary grey, white or mottled pig iron, or from any other kind of cast iron, such as "scrap" cast iron. The cast iron is made the anode of an electrolytic cell, whilst the cathode is made of wrought iron or other suitable material, and a "suitable electrolyte" is used. The iron that is deposited by the passage of an electric current from a dynamo, upon the cathode or (when the cathode is made of wrought iron) the cathode together with the deposit of iron upon it, is then heated to welding heat in a furnace and worked up as required.—H. S. P.

Improvements in the Manufacture or Production of Aluminium. G. S. Benton, London. From M. J. Berg, Paris, France. Eng. Pat. 2002, February 6, 1890. 6d.

ALUMINIUM is made by passing a powerful electric current through a mixture of ground coke, coal, or carbon and a mineral containing aluminium, such as cryolite, bauxite, sulphate of aluminium, crude clay, &c. The point of the invention consists in adding to such a mixture a certain quantity of nitrate of sodium or potassium or of sulphide of sodium or potassium, or both the nitrate and the sulphide together. About 2 parts of sodium nitrate or sulphide to 100 parts of bauxite gives a good result. The nitrate oxidises the iron and silicon which then pass into the slag, whilst the sulphide converts the iron into sulphide of iron, which also goes into the slag.—H. S. P.

Improvements in Voltaic Cells or Primary Batteries. G. R. Postlethwaite, Aston. Eng. Pat. 2273, February 12, 1890. 11d.

THE cells are arranged in a vertical or horizontal series, and the electrolyte passed from one end to the other in a continuous stream, going in its course through all the intervening cells. The whole electrolyte is thus kept in continual agitation.—E. T.

Improvements in Apparatus to be used for Electrolytic Purposes. J. C. Richardson, Clerkenwell, and T. J. Holland, Snodland. Eng. Pat. 2297, February 12, 1890. 8d.

WHEN a solution of common salt is electrolysed, caustic soda and hydrogen are given off at one plate and chlorine at the other, and are usually kept apart by a porous partition. To replace the latter, which is expensive and fragile, and increases the electrical resistance, non-porous partitions are so arranged as to catch the results of electrolysis, which all rise towards the surface, the hydrogen carrying with it the caustic soda. In one design, out of several, each electrode is covered by a sort of funnel, chlorine being drawn off at the top of one, and hydrogen and caustic soda near the top of the other.—E. T.

Improvements in Amalgamating and Extracting Gold from Refractory and other Ores. W. Crookes, London. Eng. Pat. 3532, March 5, 1890. 6d.

"The present method of extracting gold from refractory ores (such as sulphides, tellurides, arsenio-sulphides, &c., of zinc, copper, iron, bismuth, antimony, &c.) by direct amalgamation with mercury is very imperfect, as the sulphides, arsenio-sulphides, and other minerals in the ore"

cause the mercury to "flour" and "sicken," so that its fluidity is destroyed, and it either assumes a powdery character or becomes a tenacious mass. In either case, its amalgamating action is almost entirely destroyed, with the result that from 30 to 80 per cent. of the gold escapes the action of the mercury. Even when the mercury retains its active state, it will seldom take up more than one-half or two-thirds of the gold present in the ore, owing to the coat of tarnish which almost always covers the particles of gold—a coating which can only be removed chemically or mechanically—the long grinding required to remove the tarnish mechanically then tending to "flour" the mercury.

Another method of extracting gold is to roast the ores till free from sulphur and treat them with chlorine or other solvent for gold, after which the gold is precipitated from solution by suitable means, but this process is expensive. Cyanide of potassium or a soluble cyanide is sometimes used instead of chlorine, but its solvent action on gold is feeble.

The improvements consist in treating the ores with a solution of (preferably) cyanide of mercury, or some other soluble salt of mercury, as, for instance, the sulphate, which salts remove the film of tarnish and superficially amalgamate the particles of gold. When carrying out the process in this way, it is proposed to use a solution of two or three pounds of cyanide of mercury dissolved in 80 to 100 gallons of water for each ton of ore, but special circumstances may lead to varying these quantities. When the action is complete the mercury solution may be drawn off and the ore treated in amalgamating pans in the ordinary way. Heating will accelerate the action of the cyanide solution.

But where it is practicable the process is best worked in conjunction with the current from any alternating dynamo machine.

The gold ore, tailings, sulphurets, &c., are reduced to powder and mixed with a solution of any soluble mercury salt, and then a rapidly alternating current of electricity is passed through the mass, either at rest or when agitated. "The bulk of the mass is not a very good conductor of electricity, while the fine particles of gold sparsely disseminated through the mass are (as is well known) excellent conductors. . . . and the equipotential lines of force will converge towards them, with the result that more of the electric current passes through them than through the rest of the mass, and the two sides of each particle of gold act alternately as anode and cathode. On one side (the anode for the time being) sulphuric acid (if mercury sulphate be the mercury salt used) is liberated, and on the other side (the cathode for the time being) mercury is liberated; but the affinity of gold for mercury is so great that the two metals instantly unite and the gold becomes amalgamated. At the next alternation, the side of the gold particle which had the sulphuric acid liberated on it now has the mercury precipitated on it." The mercury, instead of recombining with the sulphuric acid, again attacks the gold, and thus each alternation leads to liberation of mercury on the particles of gold. In this way the finest "flour" and "thou" gold will be amalgamated, and neither does the coarseness of the ore make any difference; so long as the solution is able to penetrate to one part of the pore of gold locked up in the ore amalgamation will take place. The use of an alternating current has a further advantage in heating the mass, owing to the sudden and violent decompositions and recompositions that take place, and the heating facilitates the amalgamation.

The mercurial salt may also be used to advantage (with or without the electric current) in the grinding and amalgamating apparatus, so that the coarseness of the particles of gold from the tarnish that is on them and the amalgamation go on simultaneously, and it may also be used in concentrating and vibrating machines. H. S. P.

of zinc oxide in potash or soda lye. During charging strong granular crystals of zinc are deposited and potash rises to the surface. When charged the electrode is raised to near the surface, and in this position, which is the normal one during discharge, there is said to be no local action. The anode is of porous metallic copper, prepared by heating pulverised copper oxide with deoxidising carbonaceous substances. The E.M.F. is 0.85 volt.—E. T.

Improvements in Galvanic Batteries. M. Ancizar, Manchester. From R. Zerda-Bayon, Bogota, South America. Eng. Pat. 6223, April 23, 1890. 6d.

The cell is a carbon-zinc one, the carbon being placed in a porous pot and packed round with a mixture of dry earth containing vegetable or nitrogenous matter and sodium chloride. The electrolyte is a saturated solution of the latter salt. The salt is in some cases replaced by sulphate of alumina. For pocket use the zinc and carbon are separated by a piece of woollen or such material and enclosed in an india-rubber bag. The metals are surrounded by the above-mentioned mixture in a moist state.

—E. T.

Improvements in Secondary Batteries or Electrical Accumulators. N. de Bernardos, St. Petersburg, Russia, and J. Howard and J. H. Lloyd, Birmingham. Eng. Pat. 8534, June 2, 1890. 4d.

An improvement on Eng. Pat. 14,024 of 1887 (this Journal, 1888, 678). The bars are united to the frames by electric welding, instead of by soldering.—E. T.

Improvements in and Connected with Zinc for Galvanic Batteries. J. Moseley, Manchester. Eng. Pat. 13,463, August 27, 1890. 8d.

To diminish local action and promote more uniform wear, the zincs are made of numerous laminae, or, if of rod shape, of numerous concentric tightly-fitting tubes, each such lamina or tube being separately amalgamated. The whole is bound closely together by zinc, or preferably chonite, rivets. —E. T.

Improved Process for the Production of Pure Aluminium. A. Schmeller and A. Astfalek, Cologne, Germany. Eng. Pat. 13,486, August 27, 1890. 8d.

Tin oxide, sulphide, chloride, and fluoride of aluminium can all be reduced by hydrogen, if brought to a sufficiently high temperature. The inventors propose to obtain the latter by using an electric arc of 20,000 or 30,000 volts between aluminium electrodes, since with smaller arcs carbon must be mixed with the aluminium compounds to increase the electrical conductivity, and the aluminium so obtained is not pure. A crucible or furnace with the necessary electrical fittings is illustrated and described in the specification. It is stated that the silicon present in aluminium ores may be got rid of in the furnace as SiH_4 .

—E. T.

Improvements in Galvanic Batteries. C. E. Dutton, jun., Washington, U.S.A. Eng. Pat. 20,126, December 10, 1890. 8d.

The cell and its cover are provided with grooves and recesses so as to secure the zinc porous pot and carbon in fixed and co-axial positions, and so obtain uniform and therefore economical action on the zinc. Rubber washers, &c., are freely made use of to protect the various parts of the cell from jarring when the whole is moved about, and to render the whole watertight. The terminals of the cell are two knobs at the bottom, which are supposed to touch springs placed on the board supporting the cell.—E. T.

A New or Improved Secondary Element. K. F. Boettcher, Leipzig, Germany. Eng. Pat. 5938, April 18, 1890. 8d.

A zinc electrode, covered at the bottom and sides with non-conducting material, is immersed deeply in a solution

Improvements in and relating to the Manufacture of Insulating Compositions for Electrical Uses. T. D. Bottome, Hoosick, U.S.A. Eng. Pat. 20,289, December 12, 1890. 4d.

VERY finely powdered quartz is dried and made into a plastic mass with a solution of crude potassium or sodium silicate, colouring substances being added if desired. The mass is moulded to the required shape and may have pieces of metal imbedded in it for lamp-holders. It is then slowly dried and finally brought to a red heat. A glazing mixture may be used to give a final finish to the whole. The composition is said to be useful for insulation between commutator segments, for bases, lamp fittings, &c.—E. T.

Improvements in Electric Batteries for Lighting Miners' Safety Lamps. O. Y. Rhodes, Leeds. Eng. Pat. 21,143, December 29, 1890. 6d.

EACH lamp must be provided with internal electric ignition apparatus ending in suitable contacts on the outside of the lamp. When, through accidental extinction, it has to be lighted in the mine, it is placed on a sliding plate—which covers the top of the box—in such a way that its contacts press against others on the plate itself. The current is now made to pass through the ignition apparatus by sliding the plate, and with it the lamp, forwards on the box, the electrical circuit being thereby completed *inside* the latter. The battery is separate from the box and sliding plate which only act as a well enclosed switch.—E. T.

An Improved Carbon Stick or Pencil for Arc Lights. H. J. Allison, London. From B. B. Ward, New York, U.S.A. Eng. Pat. 616, January 13, 1891. 6d.

To prevent an arc from hissing and spluttering when run at a low voltage, the inventor coats the inside of a cored carbon with sodium or potassium silicate, preferably the former. A vapour is produced of relatively high conductivity which allows the arc to lengthen and so obviates the defects mentioned.—E. T.

Apparatus for Separating Ores and Metals by the Aid of Electricity. E. Ferraris, Ronco Igure, Italy. Eng. Pat. 1007, January 20, 1891. 6d.

TWENTY-FOUR electro magnets are arranged radially on a hub, their outer poles being all joined by a circular metal rim like a broad tyre, the whole resembling a wheel. The magnet coils are all joined in one continuous circuit like that of a Gramme armature with connexions to a commutator. When a current is led into the latter, one-half of the rim becomes of north and the other half of south polarity, the commutator keeping the position of the poles in space unchanged during rotation. The surface of the magnetised rim is notched or furnished with projections, and ore, fed upon its surface from above, falls from the wheel into heaps in different positions according to its magnetic susceptibility, the most magnetisable being carried right underneath the wheel. By the peculiar construction of the commutator, resembling in principle that of the Immisch motor, two neutral zones are left between the two magnetised segments of the ring.—E. T.

Improvements in or relating to Accumulator Plates. H. T. Cheswright, Carcassonne, France. Eng. Pat. 2360, February 9, 1891. 6d.

THE present invention is an improvement on Eng. Pat. 4087 of 1890 (this Journal, 1890, 812). The tubes employed in that specification are now placed vertically and attached top and bottom to horizontal bars. The plate is hung from the top bar, the ends of which project beyond the edges of the plate and rest in notches in suitable supports. The projections on the tubes to hold the active material in place have also been altered in shape.—E. T.

XII.—FATS, OILS, AND SOAP MANUFACTURE.

Researches on Turkey-Red Oil. Scheurer-Kestner. Bull. Soc. Ind. Mulhouse, 1891, 53—66.

ALREADY abstracted from Compt. Rend. **112**, 158—160 and 395—397 (this Journal, 1891, 471).

A Method of Determining the Consistency of Lubricating Grease. R. Kissling. Chem. Zeit. 1891, **15**, 298—299.

THE consistency is estimated by observing the time required for a rod to sink a certain distance in a compact mass of the grease at a temperature of 20°. A tin-plate cylinder or canister with a perforated or removable bottom and having a height of 120 mm. and diameter of 80 mm., is almost filled with the grease to be tested. On the surface of the grease there is placed a pointed rod (see Fig.), 30 cm. in length and 8 to 10 mm. in diameter, which is held in position by a suitable support *f*, and provided with a head *p*, from which a small pin *s* projects downwards.

AN APPARATUS FOR TESTING LUBRICATING GREASE.
